In the Tropical Health Section of the British Empire Exhibition there are exhibits in connexion with 27 tropical diseases carefully grouped according to their ætiology, and all can realise what great progress the past 20 years has witnessed. For example, a campaign with its centre at the Medical School of Khartoum has practically cleansed the Sudan of bilharzia. Among the school-children of Dongola the incidence-rate has been reduced from 20 to 6 per cent., over 10,000 children being treated with intravenous injections of tartar emetic without a single mishap. Malta fever has been traced to its source, and, widely spread as it is, has been practically stamped out among the white population. Sir Leonard Rogers has attacked Asiatic cholera and considerably reduced the mortality; the reduction of the incidence-rate, however, is a matter which still requires vigorous hygienic and sanitary measures. Typhoid fever, which in the South African war caused a death-rate of 3·6 per cent. of our troops, took toll of but 0·006 per cent. of the British troops in France in 1917, and in this, as in many other diseases due to the typhoid-coli group of bacteria, proper hygiene and sanitation have reduced the rate of incidence to very small proportions. Ankylostomiasis, which caused such a high morbidity rate among miners and others, especially the workers in the St. Gothard tunnel, is now preventable. Scurvy and beri-beri, the latter of great economic importance to large employers of native labour, can now be overcome if the diet can be controlled. Sprue still gravely impairs the efficiency of Europeans in the East, and its ætiology still remains obscure, but research workers are hopeful of final success, the results of parathyroid treatment being encouraging. Rigorous segregation of the leper is having its effect in reducing the incidence of the disease, and the treatment of yaws by arsenical preparations brings the medical man into the realms of the miracle worker with countless natives.

Yellow fever and malaria, two diseases which in the past have taken such terrible toll of life and which seemed to be a barrier to so much enterprise, have, by the self-sacrificing labour of many workers, been traced to their source, and by means of simple measures carried out with great thoroughness large tracts of country are now practically safe. In Malay alone in 19 years 32,200 lives have been saved by the reduction of the death-rate following adequate drainage, and in the same area in seven years the spleen-rate dropped from 15 to 4 per cent.

Filariasis, dengue fever, and trypanosomiasis are yielding before determined onslaughts on the mosquito and the tsetse-fly; in regard to the latter in the northern zone of Principe the case-rate was reduced in five years from 45·8 to 1·0 per cent., and in Buganda in 1914 there were no deaths, as against 400 nine years previously. Last, but not least, by strict hygiene and the destruction of infected dwellings, combined with the intravenous injection of antimony, the death-rate from kala-azar has been reduced in several areas by over 50 per cent.

These are but a few illustrations of the way in which medical science has in the past few years rendered comparatively healthy and habitable a tropical life which commenced formerly for many with the first step towards an early grave.

We publish this week the most recent notes available on the public health of Jamaica and the Falkland Islands, and in each case the story by comparison with previous official documents is one of progress.

WEST DENBIGHSHIRE HOSPITAL.—This hospital, which is in course of construction at Colwyn Bay, will soon be completed and will have 47 beds for surgical and medical cases, together with private and maternity and children's wards. The Red Cross Society gave £10,000 provided another £10,000 were raised locally, and this has been done. In addition subscriptions amounting to £4000 were obtained and these sums will probably suffice for the actual building. A further sum of £1500 has been subscribed towards the equipment.

SIGHT AND SCHOLARSHIP.

REPORT BY THE COUNCIL OF BRITISH OPHTHALMOLOGISTS.

A MEMORANDUM has been issued by the Council of British Ophthalmologists dealing with the standards of vision desirable for candidates for scholarships and teacherships under local education authorities. In the interests of the community and of the individual, the memorandum runs, it is important that scholarships and teacherships should not be granted to candidates suffering from such ocular defects as may be aggravated by long-continued study and lead to inefficiency or incapacity later in life. It is, therefore, advisable to establish, if practicable, standards of vision which shall exclude unsuitable candidates. At the same time standards should not be fixed so high as to exclude any appreciable number who might in practice prove fit. The average age of entry upon a junior county scholarship is 11 years; the holder is transferred to a secondary school for five years. Supplementary scholarships are awarded at about 13 years of age, and are held for three or four years at a secondary school. Intermediate scholarships are granted at about 16 for two or three years. Senior county scholarships are granted at the age of 18 years, and are tenable at a university for three or four years. Prospective teachers undergo training at a college between the ages of 17 and 20 years.

Errors of Refraction and Their Effect.

Myopia.—The errors of refraction of most importance in reference to education are myopia and high degrees of astigmatism. Myopia is found in about 10 per cent. of children at the leaving age in elementary schools, and in about 10 per cent. of these myopes it becomes a serious defect; in the remaining 90 per cent. of the myopes the defect causes little inconvenience apart from the necessity for wearing glasses. It is generally agreed that in many persons prolonged near work on fine objects under comparatively poor lighting is a cause of myopia, or aggravates existing myopia, especially when astigmatism is present. If preventive measures are to be initiated, and the selection of individuals likely to become unsuitable for such special duties as teaching is to be avoided, it is necessary to determine at as early an age as possible the unfavourable cases. In elementary schools cases of myopia of considerable degrees are found in infants under 7 years of age, but the first routine test of vision is not made until the children are about 8 years old. Of the cases examined at this age and sent to clinics, some with diminished visual acuity and considerable myopia are transferred to myope classes; others are ordered glasses and return to school, but usually not sufficient effort is made, either at the clinics or at the schools, to warn parents regarding the future of these children. At the age of 11 the child either is left to continue his education in the elementary school until 14 years old, or goes, frequently by means of a scholarship, to a school giving higher education of a more intensive kind. Successful scholarship candidates are then medically examined, and the first administrative difficulty arises in the elimination of those to be deemed medically unfit.

A child of 11 with 4·5 dioptres of myopia would by most authorities be deemed unfit for a scholarship. He must continue at the ordinary school or, exceptionally, go to a myope class. A child of this age with 1·5 dioptres of myopia would be deemed fit for a scholarship. Between these limits of 4·5 and 1·5 dioptres of myopia a decision has to be given on many difficult cases. Many young myopes have good visual acuity with correcting glasses, and apparently healthy fundi, yet their defect is often progressive. The determination in all young myopes of the rate of progression is most important. The previous history, however, is often defective. It may be known that the child has worn concave glasses for some time, or, at best, there may be a record that vision was tested at the age of 8 and found normal. More accurate records would be of great value, and it is desirable that such should be kept.

Astigmatism of considerable amount may cause want of efficiency, especially in those engaged in an occupation such as teaching, which involves much close or fine work. With very high degrees of this defect, visual acuity, even with correcting glasses, is usually subnormal.

Recommendations of the Ophthalmic Committee.

The experience of the ophthalmologists is embodied in the following recommendations:—

Visual Acuity.—In all candidates for scholarships and teacherships the visual acuity, with correcting glasses, should be not less than 6/9 in the better eye.

Myopia.—A child of 11 with less than two dioptres of myopia in either eye should be passed. A child of 11 with more than two and less than three, on probation, should be re-examined every six months. A child of 11 with three or more dioptres of myopia in the better eye should be rejected for scholarship training. At the age of 15 those with more than four dioptres of myopia in the better eye should be deemed unfit to train for the teaching profession. Entrants to training colleges, who are, as a rule, about 18 years of age, with more than five dioptres of myopia in the better eye should be rejected.

Astigmatism.—Simple myopic astigmatism exceeding three dioptres in the better eye should be a cause of rejection of candidates both for scholarships and for training as teachers. In cases of compound myopic astigmatisms, unless the myopia is stationary, astigmatism of even two dioptres may be a cause of rejection. Cases of hypermetropic astigmatism should be rejected only if visual acuity, with correcting glasses in the better eye, is less than 6/9.

Hypermetropia.—This defect should not be a cause of rejection unless vision, with correcting glasses in the better eye, is less than 6/9.

Special Cases.—If there is only one eye, or if there is only one useful eye, the other being amblyopic from non-progressive disease, which in no way affects, or is likely to affect, the good eye, the case should be judged on the condition of the good eye. In the case of candidates for university and technical senior scholarships, or those intending to specialise as teachers of certain technical subjects, greater latitude may be allowed after consideration of special circumstances as to nature of work, the condition of the candidate's eyes in other respects, &c.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Co. Galway Health Scheme.

A SCHEME brought forward by the Co. Galway Board of Health for the reorganisation of the health services of the county has roused great opposition among the members of the medical profession in the county. It is proposed to reduce the number of dispensary districts from 44 to 28 by a process of amalgamation and rearrangement, and to reduce the number of medical officers by 11. At a representative meeting of the Co. Galway medical practitioners held last week in the Railway Hotel, Galway, at which Dr. T. B. Costello, Tuam, presided, a resolution was adopted declaring the scheme absolutely unworkable from the medical point of view for the following reasons: (1) the dispensary areas in the Co. Galway are at present too large, and as comparable with other districts in Ireland they are almost double in rural population; (2) the amalgamation will increase the number of "red ticket" cases, lessen the attention that people in rural districts can get, increase the necessity for hospital accommodation, and place the people in grave danger in times of epidemics. Resolutions were also passed to the effect that an economical provision of seven cottage hospitals or clearing stations is necessary in certain areas to deal with emergency work, and to protest against further schemes of amalgamation for any county until the matter is dealt with on a national basis by well-considered legislation. A committee was appointed to watch over the interests of the medical practitioners of the county.

The Unworkable Size of Some Dispensary Districts.

Dr. T. Hennessy, medical secretary of the Irish Medical Committee, said it was always considered in Leinster and parts of Munster that any district with an area of more than 25,000 statute acres and a population of between 2000 and 3000 could not be efficiently worked. In all the schemes that were ever considered in Dublin, the one thing that everybody agreed upon was that in Connacht most of the districts were vastly too big. They had districts of 40,000 and 60,000 statute acres, with populations running up to 6000. No man was supposed to do more than 2000 people in an urban area, where they were all close together. When they had a bigger population scattered over 60,000 acres they could only do rush work. They would in these circumstances see their patients once, but not a second or third time. As a matter of fact, one dispensary district in Co. Galway—namely, Oughterard, has an area of 70,085 acres, which is supposed to be adequately attended by one medical officer. Rounelstone, with 104,753 acres, has two medical officers; Spiddle, with 63,435 acres, Athenry, with 56,440 acres and a population of 5916, Bullaun, with 55,862 acres, and Lettermore, with 44,555 acres and a population of 8030, have one each. It is manifestly impossible that the people scattered over these enormous areas, much of which, in the western part of the county at any rate, is bog and mountain without roads, should receive adequate attention under present conditions. To render the facilities for medical attention even more imperfect than at present is a retrograde step.

The Asylum Strike in Co. Donegal.

The Committee of the Tirconaill Mental Hospital having been able to obtain a staff of attendants to take the place of those who recently went on strike, has taken the step of dismissing all those who ceased work. At the same time the committee reserves power to deal as is thought best with all applications for re-employment. It is said that this dismissal abrogates any pension rights the late attendants may have had.

Irish Medical Association.

The Council of the Irish Medical Association has nominated for re-election as President and Vice-President of the Association respectively, the present officers, Senator W. O'Sullivan, of Killarney, and Prof. F. C. Purser, of Dublin.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Annual Congress of the Ophthalmological Society of the United Kingdom.

THE Annual Congress of the Ophthalmological Society of the United Kingdom is being held this week in Glasgow under the presidency of Dr. A. Maitland Ramsay. The choice of Glasgow for the Congress coincides appropriately with the centenary of the Glasgow Eye Infirmary, to which some reference has already been made in THE LANCET. The proceedings extend over three days, May 1st to 3rd, and the discussions take place in the Department of Zoology of the University, which also houses the scientific exhibition in connexion with the Congress. By the time my letter appears in print the Congress will be in full swing. The programme is an extensive one, and should be productive of much interesting material. After the members have been welcomed by Sir Donald MacAlister, the morning of the 1st is devoted to a discussion of the physiology and pathology of the pupil reactions, to which Dr. Edwin Bramwell contributes. A series of short papers on various subjects occupy the Society in the afternoon, and in the evening the members dine together. On the morning of May 2nd a clinical meeting is being held in the Eye Infirmary. After the business meeting in the afternoon, a reception is to be given at the University by the Principal and Lady MacAlister. The evening session is devoted to a number of short papers and demonstrations. On the morning of May 3rd a third series of short papers will occupy the attention of the Congress. An interesting museum has been collected for the Congress. In addition to purely clinical exhibits, Prof. T. H. Bryce has provided specimens showing the development and anatomy of the eye, and Prof. Graham Kerr a series of microscopic specimens illustrative of the comparative anatomy of the eye.

Edinburgh Post-graduate Class in Insulin Therapy.

It was recently arranged to hold a post-graduate class in the Royal Infirmary during the first complete week of each month for the study of insulin therapy, particularly in relation to the use of insulin by the general practitioner. A beginning was made in March in the wards under the care of Prof. Meakins. The class, which was limited in numbers to ten, was fully attended and met each morning for a period of two hours. The more theoretical aspects of the disease were discussed and at the same time the opportunity was given for studying the severe cases under treatment in the wards. One afternoon was spent with Dr. Murray Lyon at the Diabetic Out-patient Clinic, where many of the milder cases are treated as out-patients and former ward cases kept under observation. These patients were of special interest to practitioners, for here it was conclusively demonstrated how effective treatment can be when intelligent coöperation between patient and physician exists. These diabetics are supplied with such diet tables as they require, and are instructed how to test their urine and administer their own insulin with the most satisfactory results. Emphasis was laid on the fact that diabetes can be thoroughly treated without resort to blood-sugar estimations, and these cases demonstrated that a more practical and even more effective control can be maintained by frequent examinations of the urine. Attention was directed also to the careful construction of diet tables. Much has been accomplished in the clinic by the use of standard diet tables, suited to the varying types of diabetics met with, and this in itself has done much to simplify treatment by the busy practitioner. Two afternoons were spent in the biochemical laboratory of the Royal Infirmary, where demonstrations were given of a simplified method of estimating the blood-sugar which could be readily carried out by the practitioner should he so desire. Instruction was also given in a new and more accurate method for the estimation of sugar in the urine. The class should prove of the utmost value to practitioners in the handling of diabetic cases in general practice.

Necessitous School-children.

There are two official bodies on whom the care of necessitous school-children is a charge—the education authorities and the Poor-law authorities—and while their objects to some extent overlap, the administration of these two bodies is entirely separate. On the part of the education authorities there has been recently some doubt as to the scope of the rights and duties of each, and to make the present position clear the Scottish Education Department issued on April 14th a revised circular (No. 67) on the feeding and clothing of necessitous school-children, and the Scottish Board of Health have thought it desirable to publish simultaneously a short summary (circular No. IV., 1924) on the present legal and administrative position from the point of view of the Poor-law authorities. The crux of the problem lies in this, that while it is the statutory duty of the education authorities to provide efficient education, a hungry stomach and a receptive brain are physiologically incompatible, and therefore the education authority must undertake to provide equipment and service for the preparation and supply of meals to pupils. In certain specified cases only is the cost of the meals defrayed out of the education fund. The primary concern of the Poor-law authorities on the other hand, is the relief of destitution, and thus where the persons to be relieved are persons of school age, both sets of authorities have obviously a common status. These circulars contain helpful advice as to the most efficient method of obtaining coöperation towards the common goal—namely, the health and development of the children. It is suggested that where relief is applied by the Poor-law authority the education authority might supply the accommodation service and cooking apparatus, and in point of fact in certain areas, as, for example, in Glasgow, an arrangement of this sort has been in operation for some time with excellent results. The principles of coöperation which are outlined in the circulars should be helpful to the efficient administration of the statutes.

BUCHAREST.

(From our own Correspondent.)

Improvement of the Workmen's Insurance System.

A Congress of Rumanian physicians was held lately in Czernowitz, the capital of Bukovina, a part of the former Austro-Hungarian empire. The chief topic of discussion was the improvement of the workmen's insurance system, which in its present form leaves much to be desired. The Government was represented by the Minister of Public Welfare and Health, Mr. Marzescu, who opened the Congress with the statement that the Government has been and always will be ready to make monetary sacrifices in the interests of public health and welfare. The Congress discussed the ways and means of improving the system of workmen's compensation in Bessarabia and the old kingdom of Rumania, where at present insurance is at a very primitive stage, as the Minister admitted. He stated that, on his proposal, a law had been drafted providing that all persons seeking relief at mineral springs, inside or outside the country, should, regardless of their financial status, obtain a reduction of 75 per cent. in the railroad fare within Rumania. The necessity for taking the baths or staying at a climatic resort has to be certified by an official physician, in towns by the medical officer, in villages by the district physician. Members of the workmen's insurance companies pay no fare when going to the baths for their health.

Difficulties of Country Practice in Bessarabia.

Dr. Stefanescu, chief medical officer of the Province of Bessarabia, spoke about the great shortage in the number of country doctors. He said that in more than 100 districts the position of district physician is vacant. In Bukovina, out of 40 districts these positions are filled in 18 only. This is largely due to the small salary paid by the State. Energetic efforts will be made by the health officer of Bukovina and Bessarabia to secure salaries large enough to maintain a physician and his family. At present the cities are crowded with doctors, many of them living a life of poverty rather than become district physicians. The risks to public safety in these territories are also largely responsible for the shortage of rural doctors. Mr. Marzescu stated that on his return to Bucharest his first task would be the solution of this important problem. Several weeks ago a new disease developed in Bessarabia, which resembles malaria, but is caused by a hitherto unknown fly, and not by mosquitoes. The bite of this fly causes a febrile disease that lasts from four to six days and is accompanied by nasal bleeding and a petechial eruption on the lower extremities, chest, and abdomen. Because of the lack of physicians there have been about 16 fatalities, all of which could have been prevented. In districts where physicians have been available not one patient succumbed. This lesson cannot fail to impress the Government and will result in raising salaries sufficiently to attract younger physicians to settle in the country. Luckily the epidemic is over, and it is hoped that next year there will be no recurrence.

The Rise of Infantile Mortality in Transylvania.

The deplorable condition of public sanitation in Transylvania, the largest province of Rumania, is evidenced by the request of Dr. Nicolau Popovici, chief medical officer of the county of Bihar (at present also the political prefect of the county), for help from the Government. He states that unless active and energetic measures are taken the mortality in the villages, already most serious among the children, will rise to an alarming extent. The number of births is decreasing. In July 49·87 per cent. and in August 57·21 per cent. of the new-born children died. This high mortality-rate is partly due to epidemic diseases and partly to the great number of drink-shops, which is still increasing. In Vaskoh, a village with 888 inhabitants, there are 17 brandy shops. Brandy is cheap, a litre (two pints) selling for 35 or 40 lei, approximately 10–12 pence. Besides this almost every farmer brews his own plum brandy. In consequence alcoholism is rampant and the majority of babies are weakly and suffer from rickets. Dr. Popovici recommended that the administrative committee of the county should send a memorandum to the Government to urge the refusal of licences for the sale of brandy.

Tuberculosis Exhibition in Bucharest.

A tuberculosis exhibition will be held in Bucharest in the course of the year. The National Association for the Study and Prevention of Tuberculosis and the Committee on the Prevention of Tuberculosis of the Charity Organisation Society have decided that, in view of the widespread interest in the subject of consumption, as shown by the working of the anti-tuberculosis associations formed in all provinces of the country, and the increasing desire to provide better conditions for consumptives in many cities, it is time to gather together an exhibition which will show just what has been accomplished in this country in fighting the great white plague. The exhibition will be so arranged that it will present, through diagrams, photographs, and models, a picture of the progress being made in the fight against tuberculosis, and at the same time will show the need for further effort.

Gastric Disorders and Diabetes.

Prof. Dr. I. Constantinescu, of Bucharest, said at a recent meeting of the Medical Society that in not a few cases of diabetes gastric symptoms were common, and these were usually considered to be the consequences rather than the cause of the diabetic condition. In a case treated several years ago, however, for atony of the stomach, after the employment of lavage the patient improved so much that Dr. Constantinescu resolved to investigate the relationship of stomach disorders and diabetes. Since then he has treated the stomach in 13 cases of diabetes. Seven of these have been under observation for more than two years. In all a definite catarrhal process was found. All of them were helped by lavage. The sugar content of the urine was reduced and the patient's general health always improved. In almost all of the cases there was an immediate reduction of the thirst and of the polyuria. In all of them, too, a good but not voracious appetite was noticeable. Symptoms of restlessness and bad temper disappeared promptly.

THE BRITISH EMPIRE CANCER CAMPAIGN.—A meeting in support of the British Empire Cancer Campaign will be held under the presidency of the Lord Mayor of London at the Mansion House on Tuesday, May 6th, at 3 P.M. Among the speakers will be the Duke of York, the Rt. Hon. J. H. Thomas, Secretary of State for the Colonies, the Rt. Hon. John Wheatley, Minister of Health, Sir John Bland-Sutton, P.R.C.S., and Prof. W. S. Lazarus-Barlow.

Correspondence.

"Audi alteram partem."

SYMPTOMATIC SCIATICA AND SACRO-ILIAC DISEASE.

To the Editor of THE LANCET.

SIR,—In an annotation on this subject in your issue of April 19th (p. 815) one point seems to me to require amplification. It is there stated: "Of late years much attention has been given in the United States to the diagnosis and treatment of sacro-iliac disease; many more cases have been reported in that country than in Great Britain, where definite arthritis of the joint *from whatever cause arising* is comparatively rare." The italics are mine, and I emphasise these words, for in my experience traumatic arthritis of both lumbo-sacral and sacro-iliac joints—more particularly the latter—is not comparatively rare in this country. It is, indeed, extremely common; though, unfortunately for the victims, it is rarely diagnosed. Traumatic arthritis of these joints is a clinical entity, easily recognisable, and, except in the more severe forms, easily alleviated and often cured.

Lumbo-sacral strain is usually a more or less chronic condition, and is due to an accentuation of the normal lumbar curve (marked lordosis), or to an obliteration, even it may be to a reversal of this curve leading to the "flat-back" and vertical sacrum. The former condition, so far as I know, is nearly always postural and is rarely "acute," except in lawn-tennis players with a vigorous over-head service. The latter is usually postural, though acute onset sometimes follows prolonged anæsthesia when the lumbar spine has not been adequately supported. Either condition may provoke very severe backache; and, particularly the latter, may be a cause of intense pain "referred" down the legs. A glance at the patient's back, sitting first, then standing, will reveal the possible cause of the trouble. Whether this is the true cause or not can readily be proved in the "lordosed" case by examining the patient prone and accentuating the curve first by raising the extended legs backwards and then by raising the trunk. In the "flat-back" variety the examination is made recumbent, the legs and the trunk being raised as before. Increase in pain is diagnostic in the absence of a sacralised lumbar vertebra, enlarged transverse processes of the fifth lumbar vertebra (so that they form a false joint with the crest of the ilium), fracture of a transverse process, or arthritis due to disease (tuberculosis or osteo-arthritis)—all of which can be excluded by X ray examination. Relief from symptoms can be secured by adequate back support.

The other possible cause of pain as the result of the examination is sacro-iliac strain. This may be acute or develop slowly. Great force is not essential to precipitate an acute attack; a slip while stepping out of a bath or even pulling out the bottom drawer of a chest of drawers is adequate. Moving or throwing a heavy weight, e.g., receiving a heavy sack of coal on the back, or any fall, e.g., a slip on the stairs, will often produce a severe attack. Diagnosis is simple. The patient stands with the trunk inclined forwards, the hip and knee of the affected side flexed, the toes only resting on the ground. He usually places one hand in the small of the back for support, and there is tenderness near the "dimple" in the region of the sacro-iliac joint. The lumbar spine is held rigid with a concavity to the injured side. Sitting, the position is similar, but the weight is supported chiefly on the tuber ischii of the unaffected side. Recumbent, abdominal palpation will often reveal the presence of "Baer's sacro-iliac point." This is a point of great tenderness two inches down from the umbilicus on a line drawn from this point to the anterior superior spine.

How many patients, one wonders, have been subjected to operation for appendicitis or have been treated for "ovarian pain" on account of tenderness over this point without securing relief. If, when this "point" is discovered, the tenderness is relieved by pressure backwards on the anterior superior spine, or forwards on the posterior superior spine of the ilium, diagnosis is certain. This sign is not invariably present and then examination has to be prolonged. The leg on the unaffected side is raised with the knee fully extended (as in testing for sciatica), until the limit of painful movement is reached. The range of movement is then compared with the injured side. When the limit of painless movement is reached the foot is dorsiflexed. If this increases pain we are probably dealing with a case of true sciatica; if not, with one of sacro-iliac strain, the strain being accentuated by the pull of the hamstrings on the tuber ischii, which tends to rotate the ilium backwards on the sacrum. The sacro-iliac joint, by the way, is not a synchondrosis as usually taught, but a diarthrodial joint with a definite joint cavity, which proves the possibility of movement taking place.

If the movement described increases pain, the examination can be checked by placing the patient on the sound side, and then by pressing the ischial tuberosity forward with one hand while pulling the anterior superior spine backwards with the other. But, less frequently, the strain may be due to movement beyond the normal limit of the joint in the opposite direction. Examination must then be made by mobilising the joint in the opposite direction, which is done with the patient on the sound side. The knee is flexed and the hip is hyper-extended backwards, counter-pressure being exerted on the tuber ischii. The **Y**-shaped ligament then pulls the anterior inferior spine of the ilium downwards and rotates the body of the ilium forwards, thus laying strain on the sacro-iliac joint. Manipulation of the sound side will often produce pain on the injured side in severe cases, as it is possible thus to move the sacrum on the ilium, instead of the ilium on the sacrum as in the manipulations described.

If pain is elicited as the result of both forward and backward rotation of the ilium we are dealing with an arthritis—presumably a synovitis—of the joint; if movement in one direction only causes pain, the presumption is that a "locking" has taken place and that manipulation in the opposite direction will undo it. This is the type of case that the osteopath and bone-setter can relieve so readily. Manipulation is always worthy of a trial. But, failing this (or even if it is successful, in order to render recovery permanent), relief of symptoms obviously must depend on support of the affected joint. Fortunately, nothing nearly so drastic as the treatment suggested in your annotation is usually required. An ordinary cricketing belt, applied horizontally round the body below the anterior superior spines, will suffice in the milder cases, as also in those in which manipulation has been successful. (It can be kept in place by fastening it on to a corset.) If this is inadequate, a plate must be inserted under the strap over the sacrum and suprapubic regions. A more rigid support is given by prolonging the abdominal plate at both sides, so that a bar projects outwards, and thus secures a firm antero-posterior grip below the anterior superior spines. If made of metal a very secure grip can thus be secured under the strap, particularly if the abdominal plate is prolonged downwards so as to grip the pubic symphysis at the same time. Naturally, the longer the back-piece the more secure is the support. The disadvantage is that each case presents individual characteristics, and no "standard pattern" is possible. Each case has to be fitted separately; it is for this reason that many of the sacro-iliac supports, as made in America, fail, and, so far as I know, American surgeons do not realise the importance of the projections mentioned from the sides of the abdominal plate.

Adequate support of the type mentioned will often give relief, even if X ray examination reveals the presence of definite osteo-arthritic change which, in my experience, is very rare in this country—as your annotation remarks. Some patients require support in bed. The belt cannot be worn as it slips so easily. A binder, of the maternity type, is then applied over the lower abdomen and the upper half of the thighs, and is fastened as firmly as possible. Over this a webbing strap is applied in the position already indicated as firmly as possible, and is secured in place by safety-pins.

The question then arises, Are these cases common? I can only say that I fit anything from 70 to 100 supports a year, and I should judge that less than 5 per cent. are rejected by patients. I think this is proof positive of the value of the treatment, as no one would wear a contraption such as I have indicated unless it afforded very material relief. If only the eyes of the profession could be opened to the existence of this fertile source of pain and disability, not only would much injustice be avoided in industrial accidents, but an inestimable amount of needless suffering and disability would be alleviated if not entirely relieved.

I am, Sir, yours faithfully,

JAMES MENNELL.

Park-crescent, Portland-place, W., April 21st, 1924.

MEASLES AT ADVANCED AGE.

To the Editor of THE LANCET.

SIR,—The following case is of interest owing to the advanced age of the patient.

Mrs. ——, aged 83, was admitted here on April 4th suffering from senility and bronchitis. She was very ill and was placed in a small ward in which there was a patient who was recovering from measles. On April 13th she developed a typical attack of measles, and she died on April 17th. A daughter volunteered the information that her mother had never had measles previously.

Is there any record of measles in a patient older than this?—I am, Sir, yours faithfully,

J. BASIL COOK, M.D.

West Middlesex Hospital, Isleworth, Middlesex,
April 19th, 1924.

SCHICK IMMUNISATION IN DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—Dr. C. C. Okell and his collaborators, in their paper upon Diphtheria Outbreaks in Institutions in your issue of April 19th, refer to a previous article of mine which appeared in the *Medical Officer* (March 4th, 1922). Dr. B. A. Peters, in the same issue of THE LANCET, deals with Schick immunisation as applied to the nursing staff of the infectious diseases hospital of which he is in charge. May I state as briefly as possible my own experience of the Schick test as applied to the purposes detailed by your contributors.

Since 1921 I have consistently employed a combination of swabbing (of throat and nose) and the Schick test on the appearance of diphtheria in scarlet fever wards. I am able fully to support the statement of Dr. Okell and his colleagues that by such means the situation can rapidly be brought under control. Swabbing and the Schick test—without virulence tests—serve to divide the ward population into four classes as against six in Dr. Okell's paper. I have found that in a fever ward this is commonly sufficient. On occasion, however, we have also sought the aid of virulence tests when further discrimination seemed desirable. In a fever hospital, too, where patients in the ordinary course only stay for relatively brief periods, I have usually considered it preferable to afford the immediate protection of antitoxin to the Schick + swab + group. Active immunisation by toxin-antitoxin mixture has, however, been offered to and accepted by adult patients who had still some time to spend in hospital before discharge. With the above differences the disposal of the various groups is very similar to that recounted in the paper cited. I should add that the nursing staff working in the ward is always included amongst the "swabbed" (their Schick records are already available), and that on more than one occasion the source of infection has been traced to a Schick-negative-carrier nurse whose organisms have subsequently proved to be virulent.

With regard to the protection of the nursing staff, since the beginning of 1922, every nurse has been Schick tested on entry. During 11 months of 1922 and the whole of 1923 only naturally immune (Schick-negative) nurses were allowed to work in diphtheria wards. Although this procedure afforded a very drastic test of the value of the Schick negative reaction, it became necessary, in order that Schick-positive probationers might enter diphtheria wards, to produce active immunity amongst this group. At the present moment every member of the nursing staff is either naturally immune, or has been, or is in the process of being, actively immunised. In round numbers one-third of the nursing staff has been found to be Schick-positive; thus only one-third requires active immunisation if the validity of the negative Schick test be accepted. The following figures are of some interest:—

Year.	—	No. of cases of diphtheria admitted to wards.	No. of cases of clinical diphtheria amongst nursing staff.
1921	No discrimination of staff by Schick test.	1301	14
1922	Discrimination by Schick test commenced Jan. 28th.	1090	7
1923	Discrimination by Schick test throughout year.	1409	4

In 1923 the four nurses who contracted diphtheria were all Schick-positive probationers, who were working in scarlet fever wards, and, in the well-known manner of junior probationers, contracted the disease soon after entry. There have been instances where I have thought that the test had failed us, but I have had, on investigation and re-testing, to conclude that the technique or recording or toxin was at fault, and that the test itself is a true index of susceptibility or otherwise to *clinical* diphtheria. In this belief I am greatly supported by the critical human experiments of Guthrie, Marshall, and Moss.[1] In my experience, no indubitably negative Schick reactor has ever contracted clinical diphtheria as distinct from a transient tonsillitis associated with the presence of morphological diphtheria bacilli or a frankly "carrier" state.—I am, Sir, yours faithfully,

E. H. R. HARRIES,
Medical Superintendent, Birmingham City Hospital, Little Bromwich.
April 24th, 1924.

To the Editor of THE LANCET.

SIR,—The points raised by Dr. C. W. Hutt in your issue of April 26th were emphasised by myself two years ago in papers published in THE LANCET (1922, i., 312) and in *Public Health* (May, 1922). I pointed out that the age-groups which gave the greatest number of Schick-positive reactions exactly coincided with the age-period when the incidence of clinical diphtheria is most marked—viz., 2–5 years. Furthermore, I suggested that the public health authorities, through their child welfare and school medical services, were in a position to test and immunise that portion of the population most susceptible to diphtheria.

The Schick test and toxin-antitoxin immunisation constitute one of the most notable recent advances in the sphere of preventive medicine, and the results, which are on record, obtained during the last ten years in New York sufficiently demonstrate its value. At any rate, it is not too much to say that it is possible that the thorough systematic adoption of toxin-antitoxin immunisation against diphtheria would result in a great yearly saving of child life. May one hope that, without more ado, those who specialise in preventive medicine will use their organised services to employ an agent which is potent to prevent diphtheria? I am, Sir, yours faithfully,

Bedford-square, W.C., April 28th. T. E. DICKINSON.

AURAL VERTIGO.

To the Editor of THE LANCET.

SIR,—Dr. E. Hobhouse in his interesting letter on this subject, in your issue of April 19th, expresses surprise that in the recent discussion on vertigo at the Royal Society of Medicine "no one pointed out that perfect equilibrium is possible when the semicircular canals have been completely destroyed or rendered functionless by disease or operation." For equilibrium the labyrinths of the two sides should be equally active or equally functionless, and in the most typical cases of aural vertigo there is a unilateral lesion with preponderance of the sound labyrinth over the diseased one. The vertigo would probably come to an end if the healthy labyrinth were rendered functionless to the same extent. This might be imitated to some degree by the administration of a drug capable of diminishing the sensitiveness of the healthy labyrinth. Such a drug we have in quinine (and the salicyl compounds), and doses so small as hardly to affect the auditory part of the labyrinth can produce the desired sedative effect on the equilibrial part. In proof of this I have treated many cases of aural vertigo from unilateral lesions of the labyrinth with small doses, say one-half or even one-third of a grain of sulphate of quinine, almost invariably with relief from the vertigo. In proof that this result is due to a sedative action on the sound labyrinth I have measured the length of time necessary for the caloric induction of nystagmus and found that after treatment by means of quinine the time necessary was considerably longer than before and the relief from vertigo was due to the approximation to an equalisation of the action of the two labyrinths to which I referred in my contribution to the discussion (THE LANCET, March 1st, 1924, p. 446).

I am, Sir, yours faithfully,
JAMES DUNDAS-GRANT.
London, W., April 28th, 1924.

ANTILEUCOCYTOLYSINS.

To the Editor of THE LANCET.

SIR,—I have read with great interest the article by Dr. Ivan Manoukhin in your issue of Jan. 26th. The "self-defensive reaction" which he there describes in the treatment of malaria could, presumably, be used for other diseases. On one point I should like more information, however, and that is the function of the antileucocytolysins, and of the organ that forms them—the liver—in the defences of the body. I gather from the article that they have a defensive rôle which comes into play at a later stage than that of the leucocytolysins, but their mode of action at this later stage is not made clear.

I am, Sir, yours faithfully,
Thaba 'Nchu, S. Africa, March 15th, 1924. C. LUNDIE.

HYMENOLEPIS NANA AND *H. FRATERNA*.

To the Editor of THE LANCET.

SIR,—Joyeux, in 1920, after a survey of most of the evidence, arrived at the conclusion that *Hymenolepis nana* of man and *H. fraterna* of rodents, though apparently indistinguishable in all characters, both of the adult worm and of the egg, are yet two distinct *physiological* species. More recently, however, two Japanese investigators, Saeki and Uchimura, have denied the validity of the experiments described by Joyeux, and affirm that it is possible to infect mice with *H. nana* eggs. The original papers of these two Japanese investigators not being easily accessible, and the brief abstracts available providing little or nothing of that detailed information which is so essential in these matters, I have recently been enabled, by the kind hospitality of Dr. A. Bettencourt, to re-examine the subject. Briefly stated, I conveyed to Lisbon 57 *H. fraterna*-free mice, 30 of which I have fed on fresh *H. nana* eggs obtained from the stools of infants in the hospital attached to the Instituto Camara

---

[1] Experimental Inoculation of Human Throats with Virulent Diphtheria Bacilli, J. Hopkins Hosp. Bull., 1921, xxxii., pp. 369–78.

Pestana, the remaining 27 serving as controls. In the first batch of *H. nana* egg-fed mice, two were infected out of ten; in the second batch of 13, four were infected; and in the third batch of seven one only was infected. Thus 23 per cent. of the mice were infected—a result which is satisfactory in view of the fact that all the mice were adults and therefore largely refractory to infection. The 27 control mice showed no signs of infection, and thus the possibility of accidental infection with *H. fraterna* is entirely excluded. Saeki and Uchimura are therefore correct in their view that *H. nana* and *H. fraterna* are one and the same species (though the converse experiment of infecting monkeys or man with *H. fraterna* of mice and rats is still a desideratum), and doubtless man has become secondarily infected with a parasite which originally was associated with mice and rats alone.

Full details of the experiments referred to above will be published at an early date.

I am, Sir, yours faithfully,
W. N. F. WOODLAND,
Helminthologist, Wellcome Bureau of Scientific Research, Instituto Bacteriologico Camara Pestana, Lisboa.

April 24th, 1924.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. F. Bolster is placed on the retd. list with the rank of Surg. Capt.

Surg. Lt. N. B. de M. Greenstreet to be Surg. Lt.-Comdr.

To be Surg. Lts.: R. W. C. Bull, J. B. Horam, and G. J. Hamy.

ROYAL NAVAL VOLUNTEER RESERVE.

A. M. MacGillivray, late Temp. Surg. Lt., R.N., to be Surg. Lt., R.N.V.R.

ROYAL ARMY MEDICAL CORPS.

Capt. W. D. Whamond retires, receiving a gratuity.

TERRITORIAL ARMY.

Col. C. P. Oliver, having attained the age limit, is retired and retains the rank of Col. with permission to wear the prescribed uniform.

Lt.-Col. J. S. Warrack, from R.A.M.C.T.A., to be Col. and Asst. Director of Medical Services, 44th (Home Counties) Divn., T.A., vice Col. C. P. Oliver, who vacates on completion of tenure of appt.

Maj. A. Thomas, having attained the age limit, is retired and retains the rank of Maj. with permission to wear the prescribed uniform.

Maj. (Prov.) J. Wallace is confirmed in his rank.

Lts. A. H. Richardson and R. K. Nisbet to be Capts.

A. F. G. Guinness (late R.A.M.C.), H. A. Eadie, and W. R. S. Watkins (late R.A.M.C.) to be Lts.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Maj. G. T. Willan, from the active list (supernumerary), to be Lt.-Col.

ROYAL AIR FORCE.

R. L. C. Fisher is granted a short service commission as a Flying Officer.

INDIAN MEDICAL SERVICE.

Majs. H. S. Matson, A. Cameron, A. H. Proctor, R. T. Wells, I. M. Macrae, A. S. M. Peebles, F. B. Shettle to be Lt.-Cols.

Lt. (temp. Capt.) Vijaya Shankar Rao Pandit to be Capt.

The King has approved the retirement of Maj. C. H. Brodribb (temp. non-effective list) on account of ill-health.

SOUTH LONDON HOSPITAL FOR WOMEN.—A new wing for surgical patients at the hospital, Clapham Common, S.W., will be opened by the Duchess of York on May 22nd. This extension will entail an additional expenditure of £6000, and every effort is being made to collect this sum before May 22nd, so that Her Royal Highness may be presented with purses containing sufficient to pay for the first year's maintenance. Any wishing to present purses (£10 or over) on this occasion are asked to communicate as soon as possible with the secretary at the hospital.

THE HOSPITAL PROBLEM.

CONFERENCE AT WESTMINSTER.

ON Monday and Tuesday, April 28th and 29th, a largely attended conference of hospital, medical, Labour, and kindred organisations was held at Caxton Hall, Westminster, to discuss the best method of hospital administration and control. At the first session the Labour view was set out by Mr. Somerville Hastings, M.P., the chair being occupied by Mr. Herbert Morrison, M.P.

The Premier's Letter.

Mr. Ramsay MacDonald wrote expressing his regret at being unable to attend and welcome the speakers. He said no one could ignore the straits into which war's aftermath had placed so many hospitals. Our hospital system—if the chaos now existing could be so called—remained a symptom of our inadequate civic organisation, but it fell far short of the achievements its keenest friends and supporters desired. Pending the day when the country became more fully aware of the need of prevention of destitution and disease, we could not stand idly by and allow our curative centres to suffer from neglect. The field of hospital activity should be surveyed, and ways and means devised whereby the great services thus rendered might be pursued free from the unhealthy methods by which some of our hospitals had had to seek finance in these latter days. The needs of the time demanded the application of the scientific spirit, the coördination of effort, and the elimination of waste. He felt strongly that society had never yet appreciated and valued the labours of those great public servants who, often without fee, reward, or publicity, were striving in the spirit of true scientific research to reduce the sufferings and increase the health of our frail bodies.

The Chairman paid a high tribute to the work the voluntary hospitals had done, and said the Labour Party yielded to none in admiration of it. The great question now was whether those hospitals could meet the requirements at present existing. If it could be shown that they did and could, he would not further ask for either State or public control. The sole test was efficient and effective public service.

The Labour View.

Mr. Somerville Hastings, in presenting the Labour view, said he had constantly in mind the great mass of the men and women who made use of the voluntary hospitals, which institutions provided practically the whole of the general hospital accommodation in Great Britain. But was the system likely to last for ever? Were the conditions which brought forth the establishment and the endowments of these hospitals likely to persist? There had hitherto been in this country a very wealthy class and a poverty-stricken class, but in the future conditions would be such that the poor would depend less on the bounty of the rich, and probably the rich might have less to give. Experience had shown that social movements in the experimental stage were best managed by voluntary effort, but when such a movement became a necessity it was better to look for support to a central or a local authority. There were certain disadvantages associated with the voluntary system because it was voluntary. First, there was lack of coördination: each hospital was a law unto itself. Secondly, as many general practitioners were not associated with a hospital, continuity of treatment did not exist. Thirdly, there was the danger that the medical necessity of the patient might not be the sole consideration in selecting cases for admission to hospital; there was certainly a tendency for those in authority at these hospitals to admit under easier terms patients who happened to be sent along by subscribers. Fourthly, too much energy and resource had to be expended by administrators of hospitals in collecting halfpence. The main difficulty, however, was that the voluntary system had provided only about one-third of the hospital accommodation required to-day, and the Poor-law infirmaries which attempted to make up the deficiency did not succeed in doing so, and meanwhile the deficiency was becoming more pronounced. And patients' payments made the demand on hospital beds even greater. Among the attempts to bolster up the voluntary system was that adopted in some Northern towns, of deducting from workers' wages 1*d.* or 2*d.* per week, as agreed ; this was less equitable than a rate or tax. He contended that payments by patients tended to act as a deterrent or to rob the poorest of the necessities of life, and threatened to change hospitals into nursing homes for the middle classes. Workmen might be in this way contributing towards the cost of treatment of men better off than themselves. He did not doubt that people who were very poor considered it a disgrace and would suffer anything to hide it. Put very bluntly, he believed a man had only to be a good liar and dress poorly to enter any hospital, whatever his riches might be.

The only way out of this impasse was for the State to shoulder the responsibility of providing medical treatment for all who needed it. Labour looked upon health as a national concern, and saw the danger of leaving it to charity or private enterprise ; it desired treatment centres to be set up in outlying districts, local or cottage hospitals in the smaller towns, county hospitals conveniently situated, and national hospitals in the chief cities. It would organise intimate coöperation between all hospitals, and, where necessary, make easy transfer from one to another. This would have to be evolved by stages. Poor-law infirmaries should be taken over by local health authorities and converted into first-class general hospitals, for use without the taint of pauperism. Many of the country mansions now being offered for purchase would make good convalescent homes.

Discussion.

Viscount Knutsford said that 43 per cent. of the London Hospital patients were so poor that they could not pay anything towards the cost of their treatment. Any man, whether artisan or member of the middle class, came into the category of the necessitous poor if he could not afford to pay for the treatment he needed.

Dr. G. R. Ward (Medical Practitioners' Union) thought Poor-law infirmaries were wanted not as first-class hospitals, but as less pretentious ones to which patients could be drafted.

Mr. T. Lewis told how, in his Yorkshire locality, the workers coöperated in supporting the hospital, gradually working up to 3*d.* in the £ wages, and colliery proprietors and heads of industrial firms added to the contributions.

Miss Maud McCullum (Professional Union of Trained Nurses) emphasised the desirability of coördinating cottage hospitals in small districts and county hospitals with the national hospitals in large towns. That obtained in Denmark, and she had never seen better organisation anywhere.

Mr. L. A. Hill (Association of Approved Societies) spoke of the great need for removing the pauper taint, failing which many beds in Poor-law establishments would remain empty.

Dr. Astley V. Clarke (Leicester) said there was a large working-class element on the board of the Leicester Hospital, and they were the last persons to want a State hospital service. These men were responsible for the collection of £30,000 a year, and ran their own convalescent homes. The Labour view did not take sufficient cognisance of the mentality of the people.

Dr. Wilfrid S. Fox (St. George's Hospital) declared that patients were not admitted to hospital by anyone who knew of their means ; the latter were inquired into by the almoners. Before seeking to destroy something which was admittedly doing very good work, careful consideration should be given to what it was proposed to put in its place. Hospitals existed not only for the benefit of patients, but also for research and the training of medical men.

Lady Barrett (Royal Free Hospital) maintained that the efficiency of the voluntary hospitals was constantly growing, and that they had an enormous vitality behind them. It was quite conceivable that the State should come in to do what the voluntary hospitals had left undone.

Sir Thomas Neill spoke of the importance of the community feeling the need of the spirit of self-sacrifice.

Dr. Ethel Bentham instanced cases to show the difficulty experienced by general practitioners in getting urgent cases into hospital and also the lack of coördination. It was very difficult to find out what treatment a case had had in hospital. She protested against the indignity of the antics of students and others dressed as clowns soliciting pence for the support of the hospitals.

Mr. N. Bishop Harman spoke of the inadequate representation of the hospital accommodation of the country in the Labour Party pamphlet, which did not include beds in fever, small-pox and other hospitals, and mental institutions and sanatoriums.

Mr. G. P. Blizard declared that the Labour Party had no wish to damp down any enthusiasm for voluntary hospitals ; he pleaded for a complete system of hospitals for the country. Some hospitals were full and had a long waiting-list, while others not far away had vacant beds.

Mr. H. S. Souttar, speaking as a surgeon at London Hospital, said the only criterion for the admission of a patient was his medical or surgical need. It was hard luck that because a man had lived an industrious and careful life and saved a little money that it should be a barrier to keep him from hospital treatment when he needed it. The present requirement was an extension of the present system, and to that the Labour Party should direct their efforts.

Mr. Allen Clarke (London Panel Committee) contended that there was no reason why the benefits hospitals could confer should be restricted to the poorer classes, nor why an income limit should be set up. Private paying patients in hospitals did not finance those hospitals, and these did not provide the solution of the problem.

Dr. H. B. Morgan pointed out that the British Medical Association represented only half the profession in the country. He criticised the present out-patient departments, where ordinary patients were kept waiting in close contiguity with dangerously infective ones.

Dr. A. H. Bygott spoke as a member of the Labour Party and a M.O.H., and said the party were out to fill up the gaps on this hospital question. There was a great need for young surgeons to go and do operations at the smaller hospitals. The Labour Party, having attacked this problem, were not likely to turn back.

Mr. S. R. Lamb related the success which had been achieved in Sheffield by the hearty coöperation of the workers and the employers of labour ; the civic spirit in regard to hospitals was there very manifest, and was a great factor in the success.

Mr. Hastings briefly replied, commenting on Lord Knutsford's statement that 43 per cent. of the London Hospital patients could not contribute anything to the cost of their treatment. The hospital was founded for those very people, and the statement showed that the hospitals were gradually being utilised by people better off, even by members of the middle and professional classes. An essential point about the Poor-law infirmaries was that the deterrent spirit obtaining applied even to medical treatment, and the latter was designedly less good than that obtainable elsewhere.

The Voluntary Hospital View.

On Monday afternoon the subject of discussion was " The Voluntary View," the chair being occupied by Dr. Bygott.

Viscount Knutsford, in his opening address, said he did not suggest a continuation of the voluntary hospitals because he was connected with them, nor because he thought they had no faults and could not be improved. He believed they could easily be made to meet the present needs. If the Labour Party would propose anything which would lessen suffering more than did the present hospitals, it would receive his warm support. Was the history of State control such as to induce us to hand over our sick poor to the State? The State stood in the dock with many previous convictions for neglect against it; it had done nothing over a long course of years to see that the guardians had properly carried out their duties to the sick poor; only in recent years had the guardians taken the great steps forward which had been achieved. Guardians were not elected because of any special work in a knowledge of hospitals. He mentioned with special approval, however, such Poor-law infirmaries as Lambeth and Whipp's Cross, but said that, speaking generally, the object of guardians seemed to be to do as little as possible for the sick poor. The fact was that the people of England had learned to hate the Poor-law infirmaries, and would rather die than go into them. He criticised the inadequacy of the Government arrangements to deal with the sick and wounded in the war, and showed how much superior was the organisation of voluntary hospitals. If hospitals were controlled by the State there would be no grace added to the duty, none of that spirit which added beauty to duty. The voluntary hospitals of this country had brought to the sick poor the best medical attendance and nursing in the world. The recent committee of 12 eminent men took evidence about voluntary hospitals and stated it would be lamentable if by our apathy and folly it was suffered to fall into ruin, and they recommended a grant of a million pounds, which a parsimonious Government reduced by a half. All the progress in medicine and surgery had emanated from the voluntary hospitals; public or State-managed hospitals could not have approached such a record. If there was pressure work at voluntary hospitals it was done; there was no question of "down tools" or thought of overtime; no doctor worked with his eye on the clock. To thank a surgeon for coming down to the hospital at midnight to perform an urgent operation would be to insult him. The spirit in regard to those who came to their doors was not "What do you want?"; it was "What can we do for you?" and the object was to do it in the kindest way possible. The pamphlet issued by the Labour Party quoted the late Charles Locke's words, "The voluntary hospitals are the greatest pauperising agency in this country." But was it pauperising to help a fellow creature when he was down, to help a child when it was ill, to help a mother to get through her troubles? If so, it was time to tear up the Sermon on the Mount and go in for the cold code of the Charity Organisation Society. In the treatment of the sick there must be a standard, an ideal, to work up to. Hospitals were too often dependent on some amiable fanatic who combined with the manners of a gentleman the instincts of a felon. If there was a strong belief in the treatment of the sick in voluntary hospitals every effort should be made to strengthen the system, instead of starting something else which history had shown to be bad. Viscount Knutsford proceeded to answer the allegations of abuses which the Labour Party pamphlet contained. With regard to nursing, in four years only 47 nurses out of over 700 had resigned or been required to resign on account of ill-health. He argued that the increased demand for hospital treatment was a tribute to the kind of treatment given.

With regard to the remedy, the money was to be got shortly by a payment by everybody before reaching the age of 25 and arriving at responsibility, and there should be a scheme such as a hospital saving association to assist those who needed the hospitals. He would have taken off the income-tax figures all contributions to hospitals, and a similar deduction should be made from death duties. The general practitioner should be helped, not harmed. Surely the best plan was to strengthen what was admittedly good, rather than to change to a system which history did not support. State management would satisfy nobody.

Lord Somerleyton (the King's Fund) spoke of the improvement which the hospitals of London had steadily undergone during recent years. If rates were levied for the hospitals, voluntary subscriptions to them were practically certain to cease. Difficulties had arisen in respect of voluntary hospitals not so much because of decreased subscriptions as in consequence of increased cost of requisites; but even so, the deficits had been progressively decreasing, for whereas in 1920 the deficit was £383,000, in 1922 it was £174,000, and it was estimated that 1923 would show a surplus of about £200,000, owing to some large legacies. Even without the latter, the deficit for that year would have been only about £25,000.

Sir Alan Anderson considered the Labour Party pamphlet was well written but inhuman. A great economic revolution had been taking place in this country, whose inhabitants could no longer be sharply demarcated into rich and poor; there was now a great independent working class who were very proud of their individuality. The system of regular deductions from wages for hospital support was growing in a very satisfactory manner, and had extended to London. It was absurd to think the voluntary system was going to break down because of financial difficulties; a charge for treatment in disease was as reasonable as the provision of boots, clothing, and food for the maintenance of health.

Colonel F. E. Fremantle, M.P., argued that the big complicated London hospitals should not be taken as the model, but the cottage hospital which served the needs of a rural community with the coöperation of the general practitioner.

Mr. Canter said it was agreed that the present hospital accommodation was totally inadequate for requirements, hence it was necessary to try to find a way out. He contended that the proposals of the Labour Party had not yet really been contradicted. Two out of every three persons requiring hospital treatment were not receiving it. Many cases could only be expected to recover if they were taken from their bad home surroundings and treated in hospitals. He pleaded for hearty coöperation on the part of all interested in the question.

Dr. C. W. Saleeby spoke of the need for a more healthy mode of living, which would render hospitals less necessary. He thought too much was expended on bricks and mortar for hospitals, and too little attention bestowed on obeying the laws of health. Let all combine to work away at the prevention of disease.

Dr. H. B. Morgan contended that the Poor-law infirmaries were not the Labour Party hospitals, but were the Tory Party hospitals. It should not be beyond the wit of man to work them into an efficient auxiliary to the voluntary hospitals.

Mrs. Bond said she represented 52,000 married working women, many of whom had experienced the hardships of the present hospital system, the hours spent waiting for attention to a sick child with a husband and family waiting for their dinner at home. She alleged that many nurses suffered from flat-feet and varicose veins owing to the long hours of standing and poor food. Maternity and child welfare work was brought about by the agitation of the masses of the people, and something of the kind was needed in regard to hospitals, as voluntary work had only partially succeeded.

Miss McCullum said the Labour Party statement in regard to nurses was certainly a true bill in every respect. They were underpaid; after serving four years in a hospital she was supposed to be passing rich on £50 or £60 a year.

Mr. Somerville Hastings complained that the Labour Party pamphlet was frequently misquoted. State-controlled hospitals in such countries as Switzerland, Germany, and Austria were successful, and a great deal of original research work was done in them. The outstanding fact in this country was that there were not sufficient beds, and the question was how were they to be provided? There should be State assistance, as a poll-tax affected everybody equally and not, as it should, according to their ability to pay.

Mr. Blizard said the pamphlet represented the very carefully considered opinion of a large committee on which eminent doctors and publicists were represented.

Viscount Knutsford briefly replied.

The Doctors' View.

On Tuesday morning the chair was occupied by Mr. Blizard, when the subject was The Doctors' View.

The Chairman said the subject should really be the British Medical Association's view, for among doctors there was a great divergence of view. If a start were made de novo, the function of the doctor should be regarded as keeping the people well, not to attend them in sickness. There was a great need for team work, for a pooling not only of financial resources but of medical resources. He hoped the libel would be put to rest that directly a doctor became a public servant he lost his better feelings. The Labour Party would go a long way towards placing the management of the hospitals in the hands of the doctors themselves. The Minister of Health had already set up a committee to inquire into the inadequacy of the number of hospital beds in this country and their unsatisfactory distribution.

In a long and exhaustive address Mr. Bishop Harman dealt with a very large number of points. He said the provision of money must depend upon policy, therefore policy must be defined. The Labour Party's scheme of hospital policy consisted of 13 propositions. The policy of the British Medical Association was the result of the slow growth of opinion, and had been discussed and voted upon by the divisions of the Association. It was based upon the direct experience of men engaged in the practice of medicine, and the application of that policy to the present-day conditions would secure steady improvement in hospital work. The difference between the State hospitals on the continent and the voluntary hospitals in this country was primarily due to a different outlook upon life and organisation. The policy of the Labour Party in this respect was revolutionary, that of the British Medical Association evolutionary. The former had found but little support from doctors. He proceeded to deal in detail with the 13 propositions of the Labour Party, remarking that Nos. 2, 3, 4, 8, and 10 were common ground. He objected that the number of available beds in the country given in the pamphlet was far short of the actual truth, for it did not include Poor-law hospitals, sanatoriums, mental and special hospitals. Including these, Great Britain possessed ten hospital beds per 1000 for the 38,000,000 people, the best proportion in the world. He had a particular objection to the part of the pamphlet which dealt with what were termed "anomalies of the voluntary system," one of them being stated to be that the number of appointments in hospitals was jealously guarded, with the result that all the big hospitals were badly understaffed. The statement that preference for admission was shown to those who could pay he stigmatised as absurd.

With regard to the policy of the British Medical Association, at present there were voluntary and statutory hospitals scattered through the country, mostly without any general plan of covering the ground, and no plan of coördinated effort. The Association believed that the defect could be removed if the mechanism of consultation between the several hospital authorities were provided. But to bring all hospitals to a uniform level of State control would be to find the "least common multiple." It was considered that the local committees should be extended so as to make them the coördinating bodies for all hospital accommodation required within their areas, including voluntary, municipal, and Poor-law, provided that the areas covered by the committees should be large, and that the personnel of these committees should include representatives of all the hospitals or hospital authorities concerned. Secondly, that the terms of reference to these committees should include a survey of all the hospital accommodation of the area, a determination of its adequacy, and the coördination of all the accommodation in the area, and the recommendation of any necessary additional accommodation. The committees should not interfere with the domestic autonomy of the hospitals; each type of hospital should be encouraged to work upon those lines of local initiative which had proved so vital in hospital work. Thirdly, the scope of the Voluntary Hospitals Commission should be extended to make it a standing consultative hospitals committee for England and Wales, and it should act as between the Ministry of Health and the local committees in all matters concerning hospital policy and the allocation of any grants which might be allocated to hospitals not directly supported by the State in its various functions. The voluntary hospitals, he declared, remained the pioneers of medicine. He did not think there would ever be any lack of funds or services for those who were in need. The Association considered that every patient of a voluntary hospital who was able to make a contribution towards the cost of maintenance and medical treatment should do so, unless the contributory method of subscription was adopted as essential in industrial areas.

Mr. Harman concluded by dealing with various contributory schemes and the costs, remarking that much could be done to relieve the voluntary hospitals of a heavy charge upon their resources by more generous grants in aid of education.

Discussion.

Miss Bond (the College of Nursing) alleged that nurses had in the past been overworked and underpaid, but the College she represented was doing its utmost to raise the standard of service and remuneration, thus rendering the nurse even more a helpful colleague of the doctor in prevention and cure of disease.

Dr. E. A. Gregg (Medical Practitioners' Union) called for a better relationship between the general practitioners and the hospitals, and declared that hospitals would probably not be called upon to treat, especially in the out-patient departments, many cases now dealt with there. His union asked that the general practitioner should be allowed to go back to the hospital for a portion of his day's work, for no one recognised better than the general practitioner his own limitations.

Mr. G. W. Canter (Post Office Workers' Society) contended that some of Mr. Harman's arguments were directly in favour of what the pamphlet put forward. The Labour Party wished to coöperate with those who had greater experience than themselves, and if this meeting showed a proper spirit of coöperation tangible results in dealing with the problem would ensue. He had found that workers were less inclined towards the local tax now that the friendly societies had come forward with grants, and he found it difficult to convince them that the two combined did not pay for the treatment.

Dr. May Dickinson Berry spoke of the changed conditions of the country since the war. People who before the war had the money and continued the tradition of giving had now largely lost it, and those who now possessed it had not acquired the giving tradition. She emphasised the strong self-reliant British character as a factor in the situation, which she was the more impressed with after a considerable sojourn abroad.

Mr. R. Lindsay (British Dental Association) asserted that the voluntary system of this country in so far as it applied to dental treatment was an absolute failure. Dentists had supplied not only the services, but also the money for the support of dental hospitals, which was very unsatisfactory, and all would agree that the money should come from elsewhere. It ought to be possible to devise some means whereby an efficient public dental service could be maintained.

Dr. Alfred Cox (Medical Secretary, B.M.A.) said that in initiating this conference the Labour Party had set an example which might very well have been followed by others. It had certainly justified itself. The great question was as to whether there should be further State assistance to the maintenance of hospitals. The answer obviously was in the affirmative, and what had to be agreed was how it was to be given. Some objected to the obvious intention of some Labour people to discourage the feeling of helping oneself, preferring a pooling of resources and doing everything through a committee. He regarded Mr. Harman's suggestion as the best way out. He sincerely hoped that before the conference closed some via media would be found to enable the two parties to travel side by side.

Dr. Gordon Ward said the large hospitals in London were aggregated in a manner greatly to their disadvantage. If the Poor-law infirmaries were to be brought in, the staffs would have to be drawn from the locality. Seventy-five per cent. of the cases dealt with in the large London hospitals could be as well dealt with in the country, and he asked whether it was intended that the general practitioner should normally function in the hospital work.

Mr. Lingstrom (National Conference of Friendly Societies) hoped a result of the conference would be the appointing of a Royal Commission to inquire into the matter thoroughly. Whatever might happen, he hoped this country would be spared the German cast-iron system.

Dr. Astley Clarke (B.M.A.) said the Leicester Hospital had no paid beds and no almoner, but in that town a hospital conscience had been aroused, and in 18 months there had been collected £75,000. He thought medical students at the large teaching hospitals did not receive sufficient clinical experience, hence there should be a system of drafting such students from the large hospitals to the smaller provincial ones.

Mr. Hill (Association of Approved Societies' Secretaries) denied that the Labour Party's hospital policy was revolutionary. If an increased grant was to be obtained, it surely was reasonable to have State control. He criticised the conditions at out-patient departments.

Dr. Gordon Dill spoke of the Sussex contributory scheme, which numbered 17,000 beneficiaries, and had been very successful.

Mr. H. S. Souttar (B.M.A.) said London Hospital would welcome lay coöperation from any source, and said he considered the Labour Party pamphlet was a statesmanlike document. He expressed admiration of State and municipal hospitals and their equipment on the continent.

Mr. Harman replied.

The State and Rate-aided Hospitals.

This was the subject for discussion at the last session on Tuesday afternoon. Mr. Canter occupied the chair.

Dr. John Buchan (Bradford), in introducing it, said the hospital problem in this country in its present form owed its origin to four factors: (1) an increasing urbanisation of the population, with a deterioration of the living conditions and an incoming of many serious cases of illness requiring hospital treatment; (2) the awakening of the health conscience of the people, causing a demand for further hospital provision; (3) more care and thoughtfulness in the means for the relief of poverty; (4) the increasing improvement and complexity in medical and surgical science, bringing within scope of the hospital many cases which previously could be treated at home. A way out of the heavy demand was found in the establishment of rate-aided hospitals, and the work of these had so extended during 50 years that they now provided 75 per cent. of the hospital accommodation of the country. Admittedly there was a deficiency of hospital accommodation in all parts of the country, and he thought the need was most acutely felt in the newer industrial areas. Bradford was a good illustration of this, where the only general hospital contained less than 200 beds, and for many years the working classes of Bradford needing treatment had to resort to the Poor-law infirmary, which they did unwillingly. After the war, the Poor-law authorities and the city council conferred, with the result that the infirmary, containing 1000 beds, was handed over for use by the council as a general hospital. In 1920 the admissions numbered 3804, in 1921 4482, in 1922 5141, and in 1923 5608, both patients on the order of the relieving officer and those recommended by general practitioners being admitted. The institution had now gained for itself a high local reputation. He had much to advance in support of rate-aided institutions, specially instancing the brilliant advances made by the officers of the R.A.M.C. in the last 30 years. At Bradford an attempt was made to bring the general practitioner into the scheme, but he did not come; usually his life was too busily occupied.

Dr. Gregg, dealing with the last point, thought it a great pity that the general practitioner should have to work so many hours a day in order to make a living.

Mr. Harman reminded the meeting of the attitude of the B.M.A. on the Bradford matter, and on the general question declared that the desire was for the work of the State in this connexion to be directed into profitable channels.

Sir Thomas Neill emphasised the necessity of the beds now empty in State institutions being utilised, and urged that no further time should be spent in conferences, but action should be taken without further delay.

Colonel Fremantle, M.P., said the difficulty which Parliament would at once point out was that hospital provision was asked for for those who could pay as well as for those who could not, and if hospital treatment was to be free to all classes it would mean an expenditure of many hundreds of millions of pounds a year. He advocated the linking of the finance of this on to the present system of national insurance.

Mr. Lesser agreed that if the financial part of the problem could be settled, many of the other difficulties would disappear. He thought it was questionable whether Colonel Fremantle's financial idea was practicable, but it might be possible to develop the matter along the lines of the Hospital Saving Association.

Dr. G. E. Carter, in a general review of the situation, said he had worked in Bradford Hospital, and the infirmary there was largely supported by mill-owners, whose workpeople received treatment there, and those owners thereby made a very good investment.

Dr. C. Buttar did not see why the hospital question should not be set on its legs on voluntary lines; he would like to see the hospitals run without any State aid at all.

Resolutions.

After considerable discussion the following resolutions were carried without dissent (Lord Somerleyton, Mr. Buchanan, and some others intimating their intention not to vote either way, as they had no authority from their respective bodies).

1. The accommodation, equipment, and finance of hospitals generally are inadequate, and must be supplemented.

2. The geographical distribution of hospitals is uneven, leading to overlapping and the lack of coördination. The unit of such coördination should be such as to include a sufficiently large population.

3. There should be a closer relationship between voluntary hospitals themselves, between the voluntary hospitals and the various hospitals provided by local authorities, between the curative and preventive medical services, and between the hospitals and the private medical practitioner.

4. Some form of public assistance is essential if a complete and adequate hospital system is to be maintained, and developments should be directed to preserving what is best in the present voluntary system.

5. The infirmaries at present under the Poor-law should be thrown open to all citizens and removed from all taint of the Poor-law.

Organisations Represented.

The following organisations were represented at the conference :—

British Medical Association; Medical Practitioners' Union; Medical Women's Federation; Federation of Medical and Allied Services; The Sheffield Joint Hospitals' Council; Montagu Hospital, Mexborough; British Dental Association; Royal British Nurses' Association; The College of Nursing, Ltd.; National Council of Trained Nurses of Great Britain and Ireland; The Professional Union of Trained Nurses; Queen Victoria's Jubilee Institute for Nurses; The General Nursing Council for England and Wales; Joint Committee of Approved Societies; The National Association of Trade Union Approved Societies; National Conference of Industrial Assurance Approved Societies; The Association of Approved Societies; National Association of Insurance Committees; National Federation of Employees' Approved Societies; The Incorporated Association of Approved Society Secretaries, Ltd.; National Conference of Friendly Societies; Panel Committee for the County of London; Hospital Saturday Fund; King Edward's Hospital Fund for London; The Hospital Saving Association; The British Charities Association; The British Red Cross Society; Standing Joint Committee of Industrial Women's Organisations; The People's League of Health; The League of Mercy; Royal Institute of Public Health; British Hospitals Association; St. George's Hospital; St. Bartholomew's Hospital; London Hospital; St. Thomas's Hospital; University College Hospital; Executive Committee of the Labour Party; Labour Party's Advisory Committee on Public Health.

THE LABOUR VIEW OF THE POSITION OF HOSPITALS.

IN the course of the conference on the Hospital Problem at Caxton Hall reference was made to the statement of policy of the Labour Party with regard to hospitals.[1] This pamphlet was noticed in THE LANCET (1922, i., 808). For the convenience of our readers we reprint here the summary which concludes the pamphlet.

1. The Labour Movement, recognising the importance of health to individual and national well-being, considers that all hospitals, both special and general, together with allied institutions, should be so organised under one authority as to form the foundation on which a complete hospital system for the nation with sufficient accommodation to deal with all cases requiring institutional treatment can be built.

2. It would establish treatment centres in outlying districts, local or cottage hospitals in the smaller towns, one or more county hospitals conveniently situated in each public health area, and national hospitals in London and Edinburgh and other University towns.

3. It would organise intimate coöperation between all the hospitals in each public health area and also between them and the nearest national hospital. It would make arrangements for easy and rapid transference of patients from one hospital to another according to the nature and requirements of the case.

4. It would organise intimate coöperation between the medical staffs of the various hospitals, and also between them and general practitioners, making the participation of the latter an essential feature of the hospital scheme.

5. It would provide the health authorities with sufficient beds under their own control to deal with all patients for whom they have already undertaken the responsibility. (Patients suffering from tuberculosis or venereal diseases; children from the school clinics; mothers and infants from the maternity and child welfare centres; and adults under the National Health Insurance scheme.)

6. It would introduce the necessary legislation for the transference of the Poor-law infirmaries from the guardians of the poor to the local health authorities, thus placing at their disposal many beds now vacant. It would remodel these infirmaries, where necessary, equipping and conducting them in every way on the lines of the best existing general hospitals.

7. It would give voluntary hospitals the option of being taken over by the health authorities entirely, of remaining on a voluntary basis entirely, or of receiving grants from public funds conditional on efficiency and the representation of the local health authority on the boards of management. It would secure close coöperation between those remaining entirely on a voluntary basis and the public hospitals.

8. It would relieve pressure on hospital beds in the cities and towns by acquiring convalescent homes in the country, into which should be admitted cases of threatened breakdown, and patients no longer requiring hospital treatment, but not sufficiently recovered to return home.

9. It would establish free dental clinics connected with all hospitals, believing that supervision and treatment of the teeth are essential to health.

10. It would also arrange a scheme for visiting nurses and home helps in connexion with the hospital system, and lays special stress on the importance of skilled supervision and after-care of patients who have recovered, or partially recovered, from illness.

11. It would make all public hospitals free and open to everyone who would be likely to derive benefit from institutional treatment.

12. While doing this, it would insist on the treatment offered being equal to that of the best voluntary hospitals in efficiency.

13. It would endeavour to forestall the necessity for so many hospital beds by a forward social policy generally, and in particular by establishing a "national minimum," by abolishing all slums, and by undertaking a comprehensive housing scheme.

Obituary.

THE LATE DR. R. J. REECE.

A COLLEAGUE at the Ministry of Health writes as follows of the late Dr. R. J. Reece (THE LANCET, April 26th, p. 876), revealing at the same time the fine spirit of coöperation with which the official sanitary business of the country has been conducted at Whitehall :—

One is apt to forget the magnitude of the changes which have taken place in the central medical department since Reece joined the staff of the Local Government Board in 1893. There was then comparatively little outside impetus to public health measures, save when some unusual epidemic occurred or threatened. The medical staff, though distinguished and quietly influential, was a small one. At the Whitehall office you could find Sir Richard Thorne Thorne in well-earned authority as medical officer of the Board, William Henry Power, his incomparable adjutant, and Franklin Parsons, a walking encyclopædia of hygiene. There was a small body of medical inspectors, but they came there only for conferences with their chiefs, to compare notes, or, be it confessed, to gossip. Their workshops were their libraries at their own houses; and as they were strictly required, after the Hamburg cholera agitation, to reside within the four-mile cab radius they were not far apart; they knew one another more intimately at home than at the office, and to a large extent they settled between themselves the ways in which their ordinary duties were carried out. These in the main were epidemic prevention, so far as depended on the central department; vaccination administration, with all that the complicated and exact machinery that it required in the arm-to-arm period; port sanitary organisation; sanitary surveys, and like questions. In this little group Reece was a most welcome colleague. He brought us a wealth of knowledge of aspects of life we knew little of, gained from a many-sided and hard-lived existence as a student and resident at St. Bartholomew's and Cambridge, and in many non-medical regions outside. We learnt from him about emergency surgery and medicine in which he was expert, and he told us weird experiences that we had never realised could come to any house surgeon. We learnt, too, the customs of sea captains and seamen (Reece had already served his apprenticeship as a medical officer in the Port of London), the ways of the City and of A Battery of the Hon. Artillery

---

[1] The Labour Movement and the Hospital Crisis, a Statement of Policy with regard to Hospitals. Published by the Trades Union Congress and the Labour Party, 32, Eccleston-square, London, S.W. 1*s*.

Company, about cycle record-breaking, bulldogs, shooting etiquette, and good ordering of a dinner, and the value of vintages to the well-conducted life. All this and much more we acquired by his own example or in the form of word-perfect stories and character sketches, centring round himself and friends, some of whom we never met in person but felt we had known from the cradle. Perhaps, to our surprise, we quickly realised how intensely and seriously Reece had taken to his official duties, how well some of them suited his temperament, and what infinite pains he rejoiced to take in order to get them done so that no conscience could smite him or no just critic could say they should have been done better. Some of us, who used to hanker after new worlds and policies, were apt to be fretted with our limitations to those corners of public health work which the Local Government Board dealt with by supervision in minute details, and thought ourselves cramped by the title of "Medical Inspector." With Reece it was otherwise: the very position of a Government inspector—they were not then as pebbles on the beach—appealed to him. No effort must be spared for any inquiry, large or small, which he undertook. When Reece started an inspection, messengers toiled with barrow loads of official files and the postman groaned over his bags. Before he went to a district, he had charged his notebook and his memory with all that was to be learnt about it, past misdeeds of administration, troubles with the town clerk or with the sanitary officers, the men to be careful with, and the allies to seek in the event of the obstacles or opposition which he always allowed for in advance and expected to meet. For each class of work, sanitary surveys, port inspections, or vaccination visits, he first made sure of office precedents and all things that headquarters might require, then added his own points, and made himself a guiding and all-embracing code. There was the instruction to give—the 30 points which must be mentioned and brought home, usually by an appropriate anecdote, to the port medical officer or public vaccinator visited, the other 20 points to be kept in his own mind for inquiry, which as tests would infallibly prove whether official requirements and departmental orders were being properly observed, or whether—greatest of crimes—an attempt was being made to throw dust in the eyes of Her Majesty's Inspector. And, while following his code, he kept always a keen eye for the real source or person responsible for things being well done, or not done as they should be. Inspections in almost all parts of the country, made in these ways, provided Reece with an acquaintance with all sorts and conditions of men, whom he fixed in his mind ever after, with their characteristics, qualities, and hobbies, and among whom many became personal friends for the rest of his life, always to be remembered and helped, or to be called upon when their aid was needed.

In all this work of inspection, and in the aftermath of correspondence and controversy which not rarely followed it, Reece had the great advantage of securing and deserving the confidence and support of his departmental chiefs and colleagues, medical and non-medical, and; above all, the guidance and wise counsel of William Henry Power, to whose lightest word or hint we all listened. Reece was an ardent admirer of the methods by which the senior epidemiologists of that period had achieved their results—by patient labour and investigation of all attainable facts, accumulation of circumstantial evidence and their logical analysis, such as Power's own work at Hendon, Pirbright, and Fulham. We had then few bacteriological short cuts and no scientific warrant to invoke the convenient healthy carrier of infection when we were in difficulties. While keeping abreast with new knowledge and in due course adding to it, Reece always closely followed the methods of circumstantial evidence in his own investigations into outbreaks of infectious diseases. No hiatus was permitted which could possibly be filled: rather than miss a date of exposure to infection he would get up before dawn and ride through a snowstorm; to verify an entry in a notification register he would work till midnight. His greatest value to his department probably lay in his dealing with epidemics which needed prompt action. When he was sent down to an outbreak, headquarters might be certain that they would not be left long without telegrams, reports, and work to do, but headquarters could also safely take for granted that the emergency was being efficiently dealt with. Reece proved this early during the Grimsby cholera outbreak of 1893, and notably during the great typhoid outbreak in Lincoln in 1904. To his fellow inspectors, Reece's return from one of these inquiries was a perpetual joy. They had to listen—and it was good for them—to the whole story, the human events, the doings and villainies of the persons concerned, and the epidemiological facts and problems to be explained, all put before them with Reece's graphic and circumstantial descriptions—well worth the cost of the many hours of subsequent work which they were sure to have to give to help with the official report, to support the righteous, or aid in confounding the unworthy.

The period which thus comes back to memory had ceased almost before Sir William Power's retirement in 1908. Much of Reece's best and larger work was to come afterwards. He had still to take his place and his share in the expansion of the central department during Sir A. Newsholme's tenure of office, and it was during this period that his well-known investigations into poliomyelitis incidence was done. He was still to justify his civil training as well as his knowledge of army matters by his handling of the organisation which dealt with epidemic cerebro-spinal fever among the troops in this country during the war, work which meant directing preventive measures from the centre on a scale rarely before attempted. He was to find later, when public medicine further extended its boundaries on the formation of the Ministry of Health, and the present medical department was organised under Sir G. Newman, an opportunity given to him, under post-war conditions, to control those very systems of port sanitary administration, small-pox prevention, and public vaccination which he had made peculiarly his own. Here he was deferred to in doctrine and practice, and aided by a devoted section of the staff to whose work and interests he gave himself sympathetically and unsparingly. But it was in the earlier years which I have ventured to recall that his principles, views, and systems of practical preventive work became formed, his habits of accurate observation and devotion to his department were developed, and his many friendships in the public health service were made. The time when he was "on the road," as he used to term it, was, I believe, the happiest period in his busy and fruitful life.

THOMAS DALTON, M.D. EDIN., M.R.C.S. ENG.

BY the sudden death from heart failure at an advanced age of Dr. T. Dalton, Llandudno, the community and surrounding district has lost a "grand old man." A member of a well-known Cumberland family, Dr. Dalton studied in Edinburgh and Paris, and graduated M.D. of Edinburgh University in 1864, obtaining his M.R.C.S. Eng. in the same year. As a young practitioner he settled in Llandudno, and in 1914 he had practised in the town for half a century. He took an active interest and promoted every good work in connexion with the social life of the town. As far back as 1885 he was chairman of the Board of Commissioners, he was chairman of the magistrates, and was also a magistrate for the county of Carnarvon. On his retirement from active work in 1914 the town took the opportunity to express its appreciation of his loyal and distinguished services by making him a presentation in the town-hall and arranging a banquet in his honour. After the outbreak of the war he became chairman of the War Relief Committee, as well as chairman of the War Tribunal and War Savings Committee, and at a later date of the local branch of the League of Nations

Union. It was entirely owing to his efforts that the Llandudno Convalescent Home for Women was founded in 1869, and from that date he faithfully served as medical officer to the home, and from 1876 as trustee. He was an active and devoted Churchman, and took a keen interest in the R.S.P.C.A. The funeral on April 22nd provided public testimony to the pre-eminent esteem in which Dr. Dalton was held by all sections of the community—" a man whose integrity of character and uprightness were above all praise."

Medical News.

UNIVERSITY OF CAMBRIDGE.—At examinations recently held the following candidates were successful :—

DIPLOMA IN HYGIENE.

Rangaswami Aiyar Adiseshan.

DIPLOMA IN PUBLIC HEALTH.

Justin W. F. Albuquerque, Marcus H. Babington, Chinglepet Balakrishna, John S. K. Boyd (distinguished in Bacteriology). Elizabeth P. Cameron (distinguished in the Application of Sanitary Science), Anil Chandra Chatterji, Isabella C. Darling, Louisa P. Gordon, Edith M. F. McGill, Des Raj Nayar, John G. Ronaldson, Jamiat Singh, Thomas S. Stirling, Vincent T. Thierens, William J. Vickers, and Thomas Young.

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.

Part I., Physics and Electrotechnics.—Arthur R. Colyer, George R. M. Cordiner, Frederick H. Dommissè, Charles R. Enticknap, Alexander C. Fowler, Shanazar G. Galstaun, Eric E. Holdsworth, Pratap S. Khosla, Narayan H. Kulkarni, Harold A. McCoy, Archibald C. Macrae, Frank P. Montgomery, Thomas D. Overend, Jean S. Riach, Gordon D. Thomson, Richard S. Topham, Kenneth F. Vickery, John Wall, Barbara G. Wood, and John Y. Wood.

Part II., Radiology and Electrology.—George R. M. Cordiner, Frederick H. Dommissè, Norman Grellier, Eric E. Holdsworth, Narayan H. Kulkarni, Harold A. McCoy, Archibald C. Macrae, Godfrey W. Mitchell, Frank P. Montgomery, Jean S. Riach, and John V. Sparks.

UNIVERSITY OF LONDON: *Advanced Lectures in Anatomy.*—A course of four lectures on the Development of the Human Embryo up to the Appearance of the Primitive Segments will be given at King's College, London, by Dr. T. H. Bryce, F.R.S., professor of anatomy in the University of Glasgow, at 5.30 P.M., on May 15th, 16th, 19th, and 20th. The chair will be taken by Prof. J. P. Hill, F.R.S. The lectures will be illustrated by lantern-slides and models. Admission is free, without ticket.

At recent examinations the following candidates were successful :—

DIPLOMA IN PSYCHOLOGICAL MEDICINE.

With special knowledge of Psychiatry: Noel H. M. Burke, Roy N. Craig, Elizabeth C. Eaves, Anne Fairweather, Norman Moulson, Alexander Walk, and Isabel G. H. Wilson.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary Comitia of the College was held on April 24th, the chair being taken by the President, Sir Humphry Rolleston. The following candidates were admitted to the Membership, having passed the required examination :—

Guy W. Elkington, Alexander W. Hendry, William E. Lloyd, Enrico Moll, Annis G. H. Springthorpe, Charles E. V. Sutherland, Amelia MacDougall Thoms.

Licences to practise physic were granted to 158 candidates who had conformed to the by-laws and regulations and passed the Final Examination of the Conjoint Board. The names of the successful candidates will be given in the next issue of THE LANCET.

The following were elected to the Fellowship on the recommendation of the Council :—

Clifford S. White, Hugh T. Ashby, Eric Bellingham Smith, Rawdon A. Veale, Lancelot S. T. Burrell, Matthew J. Stewart, Richard A. Rowlands, Edgar D. Adrian, Charles P. Symonds, George C. Low, John A. Ryle, and Major Greenwood. Nominated by the Council under By-law XLI. (*b*): John C. G. Ledingham, F.R.S.

A communication from the Secretary of the Royal College of Surgeons of England dated April 11th, reporting proceedings of the Council of that College on April 10th, was received and entered on the minutes.—A letter from Dr. J. A. Hayward, asking that the Membership, which he resigned in 1898, may be restored to him, was read for the second time. This application was granted.—The quarterly report of the College Finance Committee was received and adopted.—Books and other donations to the library presented during the past quarter were received and thanks returned to the donors.—The President then dissolved the Comitia.

THE first conversazione of the Royal Society will be held at Burlington House on Wednesday, May 14th, at 8.30 P.M.

NEW INSTALLATION AT HARROGATE.—A new apparatus for nose and throat treatment has been installed at the Royal Baths, Harrogate. By its means the sulphur waters are atomised by compressed air at any desired temperature and pressure.

NAVAL MEDICAL COMPASSIONATE FUND.—At the quarterly meeting of the directors of the Fund, held on April 25th, Surgeon Vice-Admiral Joseph Chambers, Medical Director-General of the Navy, in the chair, the sum of £125 was distributed among the several applicants.

ROYAL SANITARY INSTITUTE.—A sessional meeting of the Institute will be held on Friday, May 9th, in the Town Hall, Tunbridge Wells, at 5 P.M., when discussions will take place on Child Welfare Work, Retrospective and Prospective, to be opened by Dr. F. C. Linton, and on Tunbridge Wells Undertakings; Water-Bearing Strata in and Around Tunbridge Wells; Rainfall and Drought of 1921, by Mr. W. H. Maxwell, A.M.Inst.C.E. The chair will be taken by Dr. Louis C. Parkes.

SLEEPY SICKNESS IN SHEFFIELD AND MANCHESTER.—In Sheffield cases of encephalitis lethargica are on the increase, and in a recent week 41 new cases and 7 deaths were notified, compared with 37 cases and 3 deaths in the previous week, bringing the total since March 10th to 127 notifications and 16 deaths. In Manchester, since the beginning of January, there were 180 cases and 27 deaths. Only five cases were reported last week, and a similar number the previous week. In Manchester 1071 fresh cases of measles were reported last week, an increase of 100 on the previous week. At the corresponding period last year the number was 111.

MANCHESTER HOSPITALS.—The coming inquiry by the Voluntary Hospital Commission into the shortage of hospital accommodation is of great interest to the Manchester and Salford community, as these two areas together are the largest hospital centre in the country outside the Metropolis. Even with the best efforts and utmost good-will to extend the number of hospital beds, it is computed that during the last 20 years there has been no increase in beds comparable to the increase of the population. In the district there are 2444 voluntary hospital beds, and it is stated that there are nearly two cases waiting for each one of these beds. Financial difficulties alone delay the contemplated additions. In 1922 the ordinary income of the several hospitals was £290,000 and the expenditure £350,000, leaving a deficit of £60,000—i.e., more than £1000 every week to be met by special grants. According to the local secretary of the Hospital Sunday Fund, the contributions by the middle classes are reasonably good. The working classes fail, probably because there is no efficient organisation for collecting from them. In Manchester and Salford the amount collected from the wage-earning classes is but one-fifth of the sum contributed in Glasgow, and only one-half of what is collected in Birmingham, Leeds, and Newcastle-on-Tyne, and considerably less than the working class contribute in Leicester—a town with a population only about a quarter of that of Manchester.

SOCIETY OF M.O.H.'S: *Maternity and Child Welfare Group.*—The annual meeting of this group of the Society will be held at Caxton Hall, Westminster, S.W. 1, on July 3rd, at 5 P.M. The subject for discussion is the Treatment of Babies Suffering from Malnutrition and the Results obtained by Ward Provision, whether Municipal or Voluntary, for such Babies. The discussion will be opened by Prof. E. Mellanby, who will speak from his experience at the Royal Infirmary, Sheffield. Dr. Donald Paterson, of the Infants Hospital, London, will follow. Dr. Janet Campbell, of the Ministry of Health, hopes to be present. In the subsequent discussion it is hoped to hear the experience of the medical officers of babies' hospitals and wards throughout the country.

Fever Hospitals Medical Service Group.—A meeting of this group was held on April 25th, at the City Hospital, Newcastle-upon-Tyne, Dr. E. W. Goodall presiding. After a tour of the hospital, conducted by Dr. H. Kerr, papers were read by Dr. T. N. V. Potts and by Mr. Neil Maclay on Three Years' Specialist Oto-Rhinological Treatment in Scarlet Fever—a Survey and Demonstration. Several illustrative cases were shown. In the discussion which followed the subject of the treatment of conditions of otitis following infectious diseases was dealt with by Mr. W. T. Gardiner and Mr. J. K. Love, from the point of view of the aural surgeon, and by the President, Dr. C. B. Ker, Dr. F. H. Thomson, and Dr. D. S. Sutherland, from the point of view of the fever hospital administrator. Dr. Ker, the medical superintendent of the City Hospital, Edinburgh, was elected President of the group for the year 1924–25.

Harveian Society of London.—A clinical meeting will be held at the Paddington Infirmary, 285, Harrow-road, W., on Thursday, May 8th, at 4.30 p.m.

Federation of Medical and Allied Services.—The annual dinner of the Federation will take place at the Langham Hotel, Portland-place, London, W. 1, on May 30th. Sir Berkeley Moynihan, the President, will take the chair and a number of distinguished guests are expected. Individual members of the Federation and members of coöperating bodies are invited to make early application to the Secretary, at 12, Stratford-place, for any tickets they may require for themselves and guests, either ladies or gentlemen. The price of the tickets is 12*s.* 6*d.*

British Society for the Study of Orthodontics.—The Society offers certain prizes, to be awarded triennially, for competitive essays. The first award will be for the three years ending Dec. 31st, 1926, for which the prizes are as follows: (1) A medal executed in silver and an honorarium of 50 guineas; (2) an honorarium of 20 guineas; (3) an honorarium of 10 guineas. The subject for the essays to be submitted in competition for this award is: The Macroscopic Changes which Normally Occur in the Jaws and Teeth of Man and in their Mutual Relations, from Birth to the Complete Eruption of the Second Permanent Molars. The prizes are open to competitors of all nationalities. Full particulars will be sent on application to the hon. secretary, 11, Chandos-street, London, W. 1.

International Society of Public Health Officers.—As a result of the recent interchange of public health officers under League of Nations auspices the decision has been made to set up an international society open to all medical officers of health who are taking part in the various interchanges organised by the League. A provisional committee, composed of members from Great Britain, Russia, France, Germany, Poland, Italy, and Ecuador has been elected to draw up the constitution. The society will have its headquarters at Geneva, and all public health officers who have already taken part in League interchanges—namely, 240 from 43 different countries—will be invited to become original members. The new society will have as its principal object the development of the League's Health Organisation. Its members will exchange information on all matters of public health.

International Conference on Industrial Hygiene.—The Swiss Organising Committee of Health Experts for the first international meeting for the study of problems of industrial hygiene has supplied the following names of those who are taking part in the Conference:—Industrial lighting and eyestrain: Mr. Gaster (London), technical report; Mr. Oblath (Trieste), general physiopathology; and Dr. Stassen (Liege), lighting in mines and miners' eyestrain. Vitiated atmosphere in workshops: Prof. L. Hill (London), ventilation (katathermometer); Mr. Kohn-Abrest (Paris), dust and smoke; and Prof. Lehmann (Wurzburg), gases. Value of fatigue tests: Mr. F. Lee (New York), chemical methods, general criticism of fatigue tests; Prof. M. Patrizi (Bologna), mechanical and graphical methods; and Mr. Wyatt (London), psychological methods. The Committee hope to be able to distribute the reports before the meeting (July 18th to 20th, 1924). Requests for information should be addressed to Prof. Cristiani, Institut d'Hygiene, University of Geneva, Switzerland.

INFECTIOUS DISEASES IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 19TH, 1924.

Notifications.—The following cases of infectious disease were notified during the week, namely: Small-pox, 93; scarlet fever, 1316; diphtheria, 537; enteric fever, 49; pneumonia, 1607; puerperal fever, 40; cerebro-spinal fever, 11; acute poliomyelitis, 1; encephalitis lethargica, 253; dysentery, 3; ophthalmia neonatorum, 119. No cases of cholera, plague, or typhus fever were notified. The cases of encephalitis lethargica, 47 more than in the previous week, were notified in the following counties: London 33, Chester 5, Derby 6, Durham 5, Essex 6, Gloucester 14, Lancaster 26, Middlesex 4, Northumberland 19, Nottingham 7, Stafford 4, Surrey 7, Warwick 33, Yorks W.R. 55; and elsewhere in smaller number.

Deaths.—In the aggregate of great towns, the deaths from influenza fell from 316 to 282. In London the deaths from diphtheria rose to 15, and those from measles, which had been 66 in the preceding week, fell to 57 last week. The deaths from influenza in London rose to 45 last week.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Budget.

On Tuesday, April 29th, Parliament reassembled after the Easter recess, and Mr. **Snowden**, the first Labour Chancellor of the Exchequer, introduced the Budget in the House of Commons. It imposes no new taxes and makes no additions to existing taxes. He said that since December, 1919, the total reduction in the National Debt, external and internal, had been over £650,000,000. As a net result since that date we had reduced our annual interest charge by £40,000,000 and laid the foundation of an improvement in credit which it was hoped would still further reduce the debt burden in the future. He felt able to be optimistic as regards the future. Unemployment was steadily decreasing. So long as the Labour Government remained in office they did not intend to ask Parliament to abolish the Imperial preferences now accorded, but they would reserve full liberty to propose the reduction or abolition of duties on the commodities to which the existing preferences applied. He had agreed with the Postmaster-General that he should make in the near future certain postal concessions at an approximate cost of £500,000 in the current year and £1,000,000 a year thereafter.

The sugar duty would be reduced from 2¾*d.* to 1¾*d.* per lb. This would cost £17,700,000 this year. The tea duty would be reduced from 8*d.* to 4*d.* per lb. The correlated duties on cocoa, coffee, and chicory would also be reduced by one-half. The increase on the dried fruit duty of 50 per cent., which was introduced in the Second Budget of 1915, would not be renewed. He proposed to abolish the duty on sweetened table waters. The duties on imported manufactured articles, commonly known as the McKenna duties, would be abolished from August 1st next. Relief would be accorded in respect of entertainment duty by abolishing the tax on payments for admission up to and including 6*d.* and by reducing the tax on payments over that amount up to and including 1*s.* 3*d.* Methylated spirits would be required to contain an additional denaturant crude pyridine to render them more nauseous and more difficult to swallow. Inhabited house duty and the Corporation Profits duty would be abolished.

The Chancellor of the Exchequer concluded by saying that he was left with an estimated surplus in hand of £4,024,000 which he felt bound to keep, more particularly as he had made no provision for any supplementary expenditure beyond that included in the original estimates of the year.

HOUSE OF COMMONS.

Tuesday, April 29th.

Final Pensions Awards.

Mr. D. G. **Somerville** asked the Minister of Pensions whether in his recent proposals for revision of the pension regulations he proposed to consider the cases of ex-Service men to whom final awards had been granted, but whose maladies in respect of such pensions had now become seriously worse; and whether he was aware that there were a very large number of such cases in which the ex-Service men concerned were receiving no assistance whatever from the State.—Mr. J. W. **Muir** replied: Cases of the kind referred to are eligible for, and in fact receive, medical treatment from the Ministry, together (if necessary) with allowances. If, as the result of treatment, it should be ascertained that the award previously made was erroneously declared final, the case is dealt with by way of amendment of the award in the manner indicated in my reply on March 27th (see The Lancet, April 5th, p. 731).

Nursing Service in Mental Hospitals.

Mr. **Hore-Belisha** asked the Minister of Health if the departmental committee appointed to consider the nursing service in county and borough mental hospitals, and in what directions it could be improved, had yet come to any conclusions and, if so, of what nature; and, if the committee had not yet reported, when it might be expected to do so.—Mr. **Greenwood** replied: This committee has practically finished its work, and I understand it hopes to report very shortly.

Foreign Decoration.—The King has granted to Dr. Reginald Gower Kirton, late Principal Medical Officer to the Egyptian Prisons Department, permission to wear the Insignia of the Third Class of the Order of Ismail, which has been conferred upon him by the King of Egypt in recognition of valuable services rendered.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETING OF SECTIONS.

Monday, May 5th.

TROPICAL DISEASES AND PARASITOLOGY: at 8.30 P.M. (In the Laboratory of the Royal Army Medical College, Grosvenor-road, S.W.)

Annual General Meeting:

Election of Officers and Council for 1924–25.

Demonstrations:

Lieut.-Colonel J. A. Anderson: (1) Types of Improvised Sanitary Appliances for Tropical Use. (2) Measurement of Heat and Sunlight in Environment.

Dr. Broughton-Alcock: (1) A Vibriothrix Simulating *Vibrio choleræ* in the Fæces. (2) Renal Abscess Demonstrating a Mycelium Occurring in a *B. coli* Infection of the Urinary Tract.

Dr. J. B. Christopherson: (1) Series of Photographs Illustrating the Distribution, Bionomics, and Clinical Features of *Schistosoma japonicum* in Japan. (From Dr. Akira Fujinami.) (2) Cercariæ in Liver of Intermediate Host of *Schistosoma japonicum*. (From Dr. Nakamoto.) (3) Section Demonstrating Male and Female Worms in Vein and Deposition of Ova from a Case of Egyptian Intestinal Schistosomiasis. (From Major W. R. O'Farrell.)

Prof. L. S. Dudgeon: Slides and Drawings Illustrating Certain Points in the Pathology of Appendicitis.

Lieut.-Colonel W. P. MacArthur: Sections of Human Liver Infected with *Hepaticola hepatica*. (Bancroft.)

Mr. J. Ramsbottom: (1) Orchid *Mycorrhiza*. (2) Demonstration of Some Points in the Life History of Yeasts.

Dr. J. Gordon Thomson: (1) A Series of Photographs Illustrating Houses in Rhodesia in which Blackwater Fever has Occurred. (2) Films Demonstrating *P. falciparum* in Blackwater Fever Cases.

Other demonstrations will be given.

Tuesday, May 6th.

ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)

Annual General Meeting:

Election of Officers and Council for 1924–25.

Cases and Specimens:

Mr. Tyrrell Gray: Case of Chronic Infective Polyarthritis in a Girl.

Mr. Muirhead Little: X Rays of a Case of Paget's Disease.

Other cases will be shown.

Wednesday, May 7th.

SURGERY: at 5.30 P.M.

Annual General Meeting:

Election of Officers and Council for 1924–25.

Communication:

Mr. W. B. Gabriel: End-results of Fracture of the Patella Treated by Various Methods.

Thursday, May 8th.

NEUROLOGY: at 5 P.M.

Pathological Meeting to be followed by the Annual General Meeting for election of Officers and Council for 1924–25.

Friday, May 9th.

CLINICAL: at 5.30 P.M.

Annual General Meeting:

Election of Officers and Council for 1924–25.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, W.

MONDAY, May 5th.—8 P.M., General Meeting and Reception. 9 P.M., Mr. Wilfred Trotter: On Certain Minor Injuries of the Brain.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, London, W.C. 2.

MONDAY, May 5th.—8 P.M., Extra Meeting. Mr. T. Thorne Baker: Photography in Industry, Science, and Medicine.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East.

MONDAY, May 5th.—5 P.M., Prof. Karl F. Wenckebach (Vienna): Angina Pectoris and the Possibilities of its Surgical Relief.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, May 5th to SATURDAY, May 10th.—CENTRAL LONDON OPHTHALMIC HOSPITAL. Mon., 2 P.M., Mr. Oliver: Conjunctivitis Excluding Trachoma. Tues., 2.30 P.M., Mr. Gibb: Trachoma. 4.30 P.M., Mr. Williamson-Noble: New Growths of the Eye. Pathology. Wed., 2.30 P.M., Mr. Levy: The Lenses of Spectacles. Thurs., 2.30 P.M., Mr. Cunningham: Corneal Ulcers.—HAMPSTEAD GENERAL HOSPITAL, in conjunction with the North-Western Fever Hospital and Paddington Green Children's Hospital. Special Intensive Course.—HOSPITAL FOR DISEASES OF THE SKIN, Blackfriars. Clinical instruction in the Outpatient Department every afternoon from 2.30 P.M. Tuesday and Friday, Venereal Clinic from 5.30 P.M. to 7 P.M.—LONDON LOCK HOSPITALS. Clinical work daily. Lectures at Dean-street as follows: Mon., 5 P.M., Mr. Gibbs: Anterior and Posterior Urethritis. Tues., 2.30 P.M., Mr. McDonagh: Treatment of Gonorrhœa and its Complications. Thurs., 4.30 P.M., Mr. Lawrence Abel: Treatment of Acute Gonorrhœa in the Male. Fri., 4 P.M., Mr. Johnston Abraham: Treatment of Gonorrhœa in the Female.—MAUDSLEY HOSPITAL. Mon., 3.30 P.M., and 5.30 P.M., Dr. Bernard Hart: The Psychoneuroses. Tues., 2.30 P.M., Dr. Shrubsall: The Practical Aspect of Mental Deficiency. 4.30 P.M., Sir Frederick Mott: The Pathology of Mental Diseases. Wed., 2.30 P.M., Dr. Mapother: Demonstration in Clinical Psychiatry. Thurs., 4.30 P.M., Dr. Sullivan: Crime and Insanity.

UNIVERSITY OF LONDON, SOUTH KENSINGTON, W.

Lectures and Demonstrations on Medical Hydrology.

TUESDAY, May 6th.—10 A.M., Dr. R. Fortescue Fox: Introductory Lecture. 11.30 A.M., Prof. M. S. Pembrey: The Regulation of Temperature in Health and Disease. 2 P.M., Dr. S. Judd Lewis: The Chemical and Physical Investigation of Waters.

WEDNESDAY.—10 A.M., Dr. R. Fortescue Fox: The Actions and Uses of Baths. 11.30 A.M., Dr. David Brown: The Pharmacology of Natural Medicinal Waters. 2 P.M., Dr. Charles W. Buckley: The British Spas, their Waters and Methods of Treatment (at the Rooms of the Medical Society, Chandos-street, W.). Free lecture to all medical men.

THURSDAY.—9.45 A.M., Dr. G. L. Kerr Pringle: Spa Treatment of the Rheumatic Group of Diseases. 11 A.M., Dr. W. Bertram Watson: The Treatment of some Common Skin Diseases by Baths and Waters.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, May 5th.—11 A.M., Surgical Registrar: Surgical Wards. 12 noon, Mr. Simmonds: Fractures and Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases. 4.15 P.M., Dr. Ackerley: British Spas and Spa Treatment.

WEDNESDAY.—11 A.M., Medical Registrar: Medical Wards. 12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr Pernet: Skin Dept.

THURSDAY.—11 A.M., Mr. Simson: Gynæcological Demonstration. 4.15 P.M., Dr. Ackerley: British Spas and Spa Treatment.

FRIDAY.—10 A.M., Dr. Drummond Robinson: Gynæcological Operations. 11 A.M., Dr. McDougal: Electrical Dept. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Dept.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE. (Prince of Wales's General Hospital.)

(At 4.30 P.M.)

MONDAY, May 5th.—Dr. J. Browning Alexander: Thoracic Pain.

TUESDAY.—Dr. F. G. Crookshank: The Management of Diabetes.

THURSDAY.—Dr. A. J. Whiting: Heart Block and Alternation.

FRIDAY.—Mr. E. Gillespie: The Recognition and Treatment of Septic Infection of the Hand.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.

THURSDAY, May 8th.—5 P.M., Mr. Richard Lake: Examination of Case (Geoffrey E. Duveen Lectures in Otology).

CHARING CROSS HOSPITAL MEDICAL SCHOOL. (University of London Advanced Lecture in Ophthalmology.)

FRIDAY, May 9th.—5 P.M., Dr. J. Van der Hoeve, Professor of Ophthalmology, Leiden: Accommodation.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.

THURSDAY, May 8th.—5 P.M., Mr. Phillips: Childbearing and Heart Disease.

ST. JOHN'S HOSPITAL, Leicester-square, W.C.

TUESDAY, May 6th.—5 P.M., Dr. Whitfield: Principles of Local Treatment.

THURSDAY.—5 P.M., Dr. Knowsley Sibley: Alopecia.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (3.30 P.M.)

MONDAY, May 5th.—(At the Children's Hospital.)

TUESDAY.—(At the Southern Hospital.) Dr. N. B. Capon: Kidney Disease in Children.

WEDNESDAY.—(At the Northern Hospital). Dr. Murray Bligh: Diagnosis and Treatment of Chorea.

THURSDAY.—(At the Stanley Hospital.)

FRIDAY.—(At the Royal Infirmary.) Mr. Guthrie: Foreign Bodies in the Air and Food Passages.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.

TUESDAY, May 6th.—4.15 P.M., Dr. W. B. Anderton: Some Sudden and Unexpected Deaths.

BRISTOL UNIVERSITY POST-GRADUATE DEMONSTRATIONS.

WEDNESDAY, May 7th.—3.30 P.M. (at the Hereford General Hospital), Dr. Carey Coombs: Treatment of Rheumatic Carditis in Children.

Appointments.

DYSON, DOROTHY M. L., M.B., Ch.B. Vict. has been appointed an Anæsthetist to the St. Mary's Hospitals, Manchester.

HOOD, W. D., M.B., Ch.B. Glasg., 3rd Assistant Medical Officer, Baguley Sanatorium.

MORISON, D. M., M.B., Ch.B. Edin., Certifying Surgeon under the Factory and Workshop Acts for the Portree District of the County of Inverness.

TRAQUAIR, H. M., F.R.C.S. Edin., Ophthalmologist to Chalmer's Hospital, Edinburgh.

Paddington Green Children's Hospital: WILLIAMSON, B., M.B., Ch.B. Edin. (House Physician); MORRISON, R. G., M.R.C.S., L.R.C.P. Lond. (House Surgeon).

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Infirmary.—Hon. Asst. Med. Electrician.

Belfast, Queen's University.—Lectureship in Anatomy.

Birkenhead Borough Hospital.—Third H.S. £100.

Birmingham, Yardley-road Sanatorium &c.—Asst. R.M.O. £450.

Bradford Children's Hospital.—H.S. £100.

Cardiff Royal Infirmary.—Two Hon. Asst. Gynæcologists.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Hon. Reg.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. £125.

Coulsdon, Surrey, Netherne Mental Hospital.—Third Asst. M.O. £400 to £500.

East Sussex County Mental Hospital, Hellingly.—Pathologist. £500. Also Jun. Asst. M.O. £350.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—H.P., Obstetric Asst., and Two H.S.'s. Each £50.

Essex Administrative County.—Asst. County M.O.H. £700.

Grimsby County Borough.—Ven. Dis. M.O. £750.

Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—Radiologist. £100.

Hertford County Sanatorium, Ware Park, nr. Ware.—A.M.O. £350.

Hôpital Français, 172, Shaftesbury-avenue, W.C.—Sen. and Jun. R.M.O.'s. £120 and £100 respectively.

Hospital of St. John and St. Elizabeth, 40, Grove End-road, N.W.—Asst. Radiologist. £50.

Inverness, Northern Infirmary.—Jun. Medical Resident. £100.

Isle of Wight Union, Newport.—M.O. and Pub. Vacc. £150.

London County Council Education Officers' Dept.—Woman Organiser of Physical Education. £696.

London Jewish Hospital, Stepney Green, E.—R.M.O. £150. Also Jun. R.M.O. £100.

London Lock Hospital, Dean-street and Harrow-road.—Surg. Reg. £100.

Loughborough and District General Hospital and Dispensary, 9, Leicester-road.—Res. H.S. £175.

Middleton-in-Wharfedale Sanatorium.—Asst. M.O. £500.

DONATIONS AND BEQUESTS.—The late Mrs. Jane Kay Hampson, of Knightsbridge, left by will, among other bequests, £1000 to the Hospital for Incurables, Mauldeth, Heaton Mersey, Manchester; £1000 to the Cancer Hospital, Fulham; £500 to the London Hospital; £500 to the National Institute for the Blind, Great Portland-street, London; and £500 to St. George's Hospital. Part of the residue will be divided between the National Institute for the Blind, the London Hospital, and St. George's Hospital.—The St. Mary's Hospitals, Manchester, have received the following legacies: £1500 from the executors of the late Mrs. Elizabeth Shufflebotham, £1946 from the executors of the late Anna Matilda Swain, £250 from the executors of the late John Greaves.—Mr. John George Litton, of Heaton Chapel, Stockport, and Manchester, has left £28,770 by will. Besides numerous small legacies he left the residue of the property for hospitals and institutions for the relief and care of the sick in Manchester and Stockport, to be selected by the executors.

Notes, Comments, and Abstracts.

COLONIAL HEALTH REPORTS.

JAMAICA.

THE estimated population at the close of 1922 was 885,692. The birth-rate for the year was 37·3 and the death-rate 22·9 per 1000. The total infantile death-rate under 1 year was 17·7 per 1000. The principal causes of death among the inhabitants of Kingston, the capital, were: Diarrhœa and enteritis, 6·7; atrophy, icterus, and scleroma of the new-born, 10·9; phthisis, 10·8; enteric fever, 7·0; pneumonia, 5·3; heart disease, 6·2; chronic Bright's disease, 4·3; cerebral hæmorrhage, apoplexy, 4·4. Matters in connexion with the health and sanitation of the island continue to receive the earnest attention of the Government. The International Health Board of the Rockefeller Foundation are actively engaged in the treatment of hookworm in the parish of St. Catherine, and it is proposed to extend operations to other parishes. During the year the chief sanitary medical officer assumed duty, and it is anticipated that an efficient sanitary staff will be organised to cope with public health conditions requiring betterment. The recrudescence of alastrim (Kaffir pox) still existed during 1922, but the mortality was abnormally low, and vaccination has proved to be a very substantial protective measure. The average rainfall for the year was 52·38 inches, which was considerably below the average for the past 50 years (76·46 inches). In Kingston the mean temperature for the 12 months was 78·7° F., the highest maximum was 93·5° in July and the lowest 64·6° in January.

FALKLAND ISLANDS.

The estimated population on Dec. 31st, 1922, was 1205 males and 937 females, total 2142. There were 55 births (30 males and 25 females) during the year, and 15 deaths (6 males and 9 females). The health of the colony was good, there being no sickness of a serious character recorded. The rainfall for the year was low. Continuous dry weather was experienced for 54 days in the months of November and December. The largest number of days on which rain fell in one month was in September. The highest temperature recorded was in December, when 69° was reached. Constant strong winds prevail during October, November, and December, rising at daybreak and falling towards evening. Severe storms are of less frequent occurrence and intensity than in the United Kingdom. The average temperature in West Falkland is higher than in the East Island. This is thought to be due to the presence of a warm current which exists in the vicinity. There is little doubt (it is remarked in the annual report) that the climate on the whole is one of the most salubrious in the world. There are neither endemic nor epidemic diseases. It has been frequently stated that there is some danger in the alleged rigour of the climate for persons predisposed to pulmonary affections, but no support can be found for the theory, and medical officers stationed in the colony have given it as their opinion that the Falklands can be recommended as a health resort for such persons. The dependencies of the colony consist of several groups of islands, comprising a total area of land and sea of more than 3,000,000 square miles. South Georgia, the principal island in these dependencies, lies in latitude 54½° S. and longitude 36° to 38° W.; it has an area of about 1000 square miles, and is a mass of high mountains covered with snow, while the valleys between are filled with glaciers which in many cases descend to the sea. The coastal region is free from snow in summer and more or less clothed with vegetation. During 1922 rain fell on 121 days, and observations show that snow falls on an average on 124 days in the year and hail on 43. South Georgia is the only part of the dependencies which is permanently habitable. It has a fluctuating population of over 1000. Five land stations have been established there by whaling companies.

THE VARIVANE SUPPORTS.

WE have received from the Varivane Co., 56, Borough High-street, London Bridge, S.E. 1, samples of the forms of support which they make for the subjects of varicose veins, phlebitis, and conditions described as synovitis, and "loose cartilage." The samples sent include a support for the calf and ankle combined, and separate supports for calf and ankle, a support for the thigh and knee, and separate supports for the knee. The appliances are all made of canvas stiffened at the lace eyelets, the object of the inventors being to produce an efficient substitute for elastic stockings. The even pressure of elastic stockings cannot, we think, ever be obtained by any other appliances, but, as both doctors and their patients know well, the life of an elastic stocking is limited by the period of its elasticity, and when the vital property is lost in one place the whole stocking tends to become useless. The material of which the Varivane supports are made is durable, and if the appliance has been properly fitted in the first place, we can understand that it should last a very long time with a considerable saving of money in comparison with the expense of using elastic devices. The stockings and other supports are easy to put on and take off, can be washed, and can be readily repaired.

BOLOGNA MEDICO-CHIRURGICAL SOCIETY.

WE have received from this Society an announcement in Latin of the festivities in celebration of the coming centenary of the Society in June. The text runs: If those who wish to be present, and cannot, will signify by letter to Prof. Dagnini their goodwill and approval, such expressions will give great gratification. And that the authorities may in return display some mark of appreciation, they will forward to the signatories a copy of the commentaries of the Society, which will be issued shortly.

MEDICAL LITERATURE FOR MISSIONARY DOCTORS.

To the Editor of THE LANCET.

SIR,—May I through your columns make known the need of medical literature by members of the medical profession who work in hospitals scattered over the world? Copies of THE LANCET or other medical papers would be greatly valued when finished with. I will gladly supply addresses to which such literature may be sent: it should not be addressed to me.—I am, Sir, yours faithfully.

B. GAMBIER PARRY,
S.P.G. Secretary for Medical Literature.

Westhaven, Leckhampton, Cheltenham, April 24th, 1924.

REGISTRATION OF MEDICAL STUDENTS.

AT a recent meeting of the Senate of the University of London it was resolved that the following paragraph be substituted for the second footnote on p. 1 of the Regulations for Matriculation, and that it be inserted in the Regulations in Medicine (Red Book, 1923–24, p. 219): "The Medical and Surgical Degrees of this University are registrable qualifications to practise, and, *though desirable*, it is not necessary that students should register as Medical Students in order to qualify themselves to enter for the examinations for these Degrees. For the Diplomas of certain other Licensing Bodies, however, registration as a Medical Student by the General Medical Council is a necessary preliminary, and students should obtain particulars from the Registrar to the General Medical Council, 44, Hallam-street, Portland-place, W. 1." The italics are ours, and indicate the words which mark the difference in the sense of this paragraph from footnote 2 to the Regulations for Matriculation set out as an appendix to the University of London Calendar, 1923–24.

PROFESSIONAL AND BUSINESS WOMEN'S HOSPITAL LEAGUE.

AT the annual meeting held at 29, Grosvenor-place recently, Miss Corry presiding, it was stated that the total membership on Dec. 31st last was 1649 benefit members, and about 250 hon. members, against 996 benefit members, and about 200 hon. members on Dec. 31st, 1922; 776 new ordinary members have been enrolled during 1923. The League was founded in 1913 to make provision in severe sickness for women who earn their living in professional and business callings. The ordinary benefits available are: (1) Four weeks' treatment in a hospital specified by the committee, either in London or in the provinces; (2) free consultation with a gynæcologist, should such a step be necessary; (3) a reduction of cost on surgical appliances. Certain cases, which do not fall into the above classes, are given special grants on a doctor's certificate. The age limit for benefit members on joining was discussed, and this was fixed at 55. Eighty-six claims were received during the year, of which 49 were met by hospital treatment, consultation, or money grants. Of the rest, 9 cases were ineligible for benefit, 15 were withdrawn, and 13 were refused.

Erratum.—In Sir William Collins's note last week on Chadwick's Later Work he is made to say: "Many of his [Chadwick's] addresses and essays were in *English*, which he wrote with ease." The italicised word should, of course, have been *French*, and we regret the printer's slip none the less that it can have misled no one.

"A SAFE LITTLE HEATING LAMP."—Messrs. Ahlmann, Ltd., inform us that the price of "Meta" N.P. Candle with wood base, No. 20, on which we commented favourably (THE LANCET, April 19th, p. 834), is 4*s.* 6*d.* This implement has been specially constructed for sterilising small surgical and medical instruments, and also for heating the contents of test-tubes.

Annual Oration

ON

CERTAIN MINOR INJURIES OF THE BRAIN.

Delivered before the Medical Society of London on May 5th, 1924,

BY WILFRED TROTTER, M.S. LOND.,
F.R.C.S. ENG.,
SURGEON AND HOLME LECTURER IN CLINICAL SURGERY, UNIVERSITY COLLEGE HOSPITAL, LONDON.

THE choice of this subject has been guided by two considerations. In the first place, the unity of structure which is so characteristic a feature of our Society, seemed to point towards some topic of which the interest is not limited to any special department of medicine. In the second place, the occasion appeared to be one, if I rightly interpret its tradition, in which a very close restriction to technical matters need not be insisted on; while if the subject chosen developed naturally towards regions outside the strictly medical field, some glance into such wider sources of interest might be, in the circumstances, legitimate.

INTRODUCTORY.

It will, I think, be admitted that the subject of head injuries is of practical interest and importance to the great majority of us, whether our work lies exclusively or chiefly in a special department of medicine, or is distributed over all. It is, however, only to a very much limited part of this large subject that I propose to invoke your attention. My primary object will be not the gross and at the same time relatively definite conditions that we meet with in immediate consequence of obviously formidable accidents, but the conditions at first sight relatively indefinite, and not obviously serious, which occur as late results or sequels to head injuries of all grades of severity. It will be convenient at once to define our subject yet more exactly. We are to consider a group of phenomena, including headache, giddiness, and other less definable sensations in the head, defects of memory, concentration and attention, alterations of disposition and mood, and certain kinds of mental deterioration. This group of phenomena is to interest us when arising after and in obvious consequence to a head injury. It will not be necessary to deal with each member of the group, as the single one of headache can be selected as the most characteristic and as fully representative of the others. What can be said of headache, the commonest of them, can be said with all reasonable probability of most, if not all, of the others. We have now pruned down our subject until it is adequately represented by that of headache as a sequel of head injury. There remains, however, one further stage of definition to be accomplished. Headache, and others of the associated group of symptoms, is common as a sequel to head injuries of all grades of severity, and bears no obvious relation to the amount of gross destructive damage that has been inflicted. In considering its significance here, therefore, it will simplify the problem if we limit ourselves to headache occurring as the sequel of head injuries of minor severity, and without evidence of local damage to the brain, either through destructive injury or in consequence of hæmorrhage. It might be thought that these restrictions of our subject have reduced it to insignificance. This is, however, far from being the case, and it is often of the utmost practical importance to recognise the fact that seriously disabling headache is a common sequel to head injuries of an apparently minor kind, in which evidence of any direct local injury of the brain has been altogether lacking.

We have, then, ultimately before us the subject of serious headache as a sequel of apparently slight or trivial head injury.

HEADACHE AS A SEQUEL OF MINOR HEAD INJURY.

It is quite a mistake to suppose that the conditions we are considering are clinically indefinite and difficult to recognise. In well-marked cases one of the most fully characteristic of clinical pictures is produced.

The Causal Injury.—There are two types of accident which fulfil the conditions we have laid down. Both are fairly common, of quite moderate severity, and seem at the time of infliction to have caused no definite or severe cerebral injury. In fact, the mildness of the whole affair often causes both patient and doctor, if one is consulted, to congratulate themselves on no harm having been done, and to ignore the necessity for precautionary treatment.

In one type the accident is a fall on the head, as, for example, from a horse. The patient develops slight concussion of the brain; there is momentary unconsciousness which is quickly recovered from, and followed by dizziness and headache, which clear up in a comparatively few hours. I may say at once that I use the term concussion, as I think it should only be used in the strict classical sense to indicate an essentially transient state due to head injury which is of instantaneous onset, manifests widespread symptoms of a purely paralytic kind, does not as such comprise any evidence of structural cerebral injury, and is always followed by amnesia for the actual moment of the accident.

In the second type of injury the violence is characteristically limited to a localised area of the skull. This may be produced by the patient accidentally running against some obstacle, by a blow from such a weapon as a stick or sword, or by the grazing impact of a bullet. In these cases concussion is characteristically absent; there is no loss of consciousness, and the patient retains a clear memory of the moment in which the injury was received. If the blow was over some part of the brain slight functional disturbances in which are capable of being manifested in symptoms, there may be transient numbness and tingling in the corresponding limb, or clumsiness in the use of it. Such phenomena are not relevant to the limited subject we are considering, and perfectly characteristic cases of traumatic headache commonly occur without them.

We have, then, a patient who has sustained one or other of these accidents. He has been shaken and is in some discomfort for a few hours or even a day or two, but has already begun to feel that, ugly as the affair seemed at the moment, no harm has been done, and then he begins to suffer from headaches.

As I have already said, I take headache as a representative symptom, ignoring for our present purpose the constellation of minor manifestations of which it is undoubtedly the most important and outstanding figure. It is necessary now to define the clinical characters of these headaches.

CLINICAL CHARACTERS OF TRAUMATIC HEADACHE.

Onset.—If headache has been a well-marked immediate consequence of the injury it may be continued into the sequelar headache we are considering. If the patient has been laid up as the result of the injury, the headache is apt to come on when he resumes active life. In any case it is often a week or two before the patient realises that he is faced with a distressing and disabling trouble that shows no tendency to early spontaneous recovery.

Occurrence.—It is usual and almost characteristic for the headache to occur in attacks which last for periods varying from a few hours even to two or three days. Between attacks the patient may feel absolutely well in every way. The attacks are apt to be brought on by physical exertion severe or prolonged, or by mental excitement anxiety or fatigue, and by such combined influences as walking in bright sunlight, or in crowded streets, and the many not always obviously exacting activities of town life.

Quality of the Headache.—The pain is of a severe throbbing, bursting character. Like that of migraine it is made worse by any effort, and by bright light or loud noise. It may prevent the patient from sleeping, but like many other kinds of headache is often brought to an end by prolonged sound sleep. During the attack the patient is usually restless, intolerant of company or of any kind of attention, and irritable. In severe cases there may be during the attack almost maniacal irritability and sometimes a semi-delirious excitement. The severest attacks do not usually last more than a couple of days.

Results of Physical Examination.—It is possible, and indeed quite common, for these symptoms to occur without there being any physical signs of definite brain injury, such as even the minor grades of sensory disturbance of cortical type, defects of finer motor coördination, or alteration of reflexes. There is, of course, nothing in the nature of the cases to prevent such a severe grade of injury being present as would produce these signs, but I wish to put emphasis on the statement that many cases of the typical headache are met with in which no physical evidence of brain injury is to be made out.

PATHOLOGY OF TRAUMATIC HEADACHE.

It has sometimes been supposed that these symptoms are due to a psycho-neurosis determined by the injury. Such an opinion has found support, in the total absence of objectively discoverable evidence of cerebral injury, in the fact that the symptoms tend to subside under rest and easy conditions and to be aggravated on the resumption of active life, and in the supposed fact that head injuries are particularly apt to lead to the so-called traumatic neuroses.

I need not criticise this hypothesis, as I shall immediately be setting before you what I regard as a definitely established organic pathology; but I may pause a moment to remark on the conception that traumatic neuroses are especially likely to follow head injuries. It seems probable that an injury is related to the neurosis it determines, as a painful and terrifying experience, the memory of which does not lapse in the normal way but becomes associated with other unassimilated memories and repressed impulses. It is clear, therefore, that the survival of an actual memory of the accident is an essential factor in the production of a neurosis. Now in a large proportion of cases of head injury (including a considerable number of the special group of cases we are considering) the onset is with concussion, and therefore, since a localised absolute amnesia for the accident is always produced by concussion of the classical type, there is no memory at all of the occurrence of the injury. This conclusion is supported by actual clinical experience, which thus confirms the view implied above, that the concussion amnesia is a true organic absence of memory caused by cerebral disturbance.

There can be little doubt, however, that these traumatic headaches are due to definite organic disturbance within the skull. The immediate pathology of headache in general, by which I mean the actual mechanism by which it is produced, has not been the subject of very much attention, though the facts available admit of a reasonably probable sketch being made. In the first place, there is no reason to suppose that disease or injury of the brain itself can be the immediate cause of headache, in the strict sense of the term. As with other serous cavities, the contained organ itself is relatively, if not absolutely, insensitive, and pain can be aroused only by disturbances of the lining membrane and its septa. As with other serous membranes, also, it is probable that the most effective pain-producing stimulus is stretching. Now the arrangement of the dural septa is such that variations in the amount of intracranial pressure and inequalities in its distribution tell on them by causing alterations in tension. Thus it comes about that headache of organic origin is a direct expression of disturbances of intracranial pressure however these may be produced. Such a conclusion is in obvious agreement with clinical experience. It is probable that in nature a reduction in intracranial pressure is but rarely the cause of headache. It is plain, however, from the arrangement of the dural septa, that a local reduction in pressure can give rise to painful stretching until the disturbance has become equalised. This, of course, is the mechanism by which is produced the headache that often follows the withdrawal of fluid by a lumbar puncture.

When a disturbance of intracranial pressure is severe or rapidly progressive the consequent headache is continuous. When the disturbance is moderate, and either stationary or only slowly progressive, the headache is apt to be only paroxysmal. This latter is the case with a certain number of slow-growing cerebral tumours in their early stages, and as we have seen is almost characteristic of traumatic headaches. As to the nature of the disturbance in the case of traumatic headaches, we have a large body of direct evidence observed at operations. On such occasions there is always some increase in the intracranial tension, but usually this is only moderate in amount, since an operation is not likely to be undertaken during the actual course of an attack. This increase of tension is associated with one or other of two conditions of the brain itself. In cases where the headache has followed an injury causing concussion, the brain is œdematous and exudes an undue amount of fluid when exposed. In cases where the headache has followed a localised blow on the head, and the region struck has been explored, the brain shows by its swelling and blood-staining that it is the seat of a localised bruising. It is highly probable, therefore, that in both cases the increase of intracranial tension is due to the brain being swollen as the result of bruising; in one type of case, probably throughout its substance, in the other type chiefly, at any rate, at the point struck. If it be granted as reasonable to ascribe traumatic headache to a disturbed intracranial tension consequent on bruising of the brain, three points yet remain somewhat obscure and in need of discussion. These are the long persistence of the symptoms, the intermittence of the symptoms, and the mechanism by which the bruising of the brain is produced.

Persistence of Cerebral Contusions.

Traumatic headaches are notoriously capable of persisting for many years, and a difficulty at once presents itself in supposing them to be due to a mere bruise of the brain. This difficulty can be met only by the recognition of a very important and perhaps the only really special principle of intracranial pathology. This principle is concerned with the unique status of the brain as the one organ in the body enclosed by a capsule which is wholly inextensible by any physiological force. When any other organ is contused and its substance distended by extravasated blood, it can swell as a whole practically without limit, so that its circulation can be liberated from embarrassment by pressure, and the effused blood carried away relatively soon. Again, it is possible for such an organ only very slowly, or perhaps never, to regain exactly its normal size, and yet in no way to be for this reason a cause of symptoms.

Neither of these possibilities is open in the case of the brain. Enclosed within its inextensible capsule, the skull, the organ can undergo compensatory swelling only to a strictly limited extent. The result is that the circulation through a contused area remains embarrassed by the extravasated material present in it, and resolution by absorption of the bruise is indefinitely prolonged. It is surprising how long after the injury the signs of contusion will remain evident in the injured area. I have myself exposed by operation an area of brain that had been bruised by the glancing contact of a bullet with the skull no less than four years earlier. The brain showed a bruise that appeared as fresh as if it had been inflicted within a few weeks. This inordinate and unique delay in the resolution of contusions is fully adequate to account for the striking persistence of traumatic headaches.

Intermittence of Symptoms.

Although the skull encapsules the brain with a certain closeness, it does not do so so closely but what a margin of accommodation is left, which permits freely of the variations in the size of the brain due to the circulatory mechanism. An encroaching lesion, therefore, such as an early tumour or a moderate contusion, may have its effects, as it were, contained entirely within this marginal space as long as the circulatory movements are tranquil and small. The moment, however, that such movement becomes active, the fact that the intracranial space is actually encroached upon becomes manifest in an evident elevation of the intracranial pressure and consequent symptoms. Patients at such a stage often observe that every repetition of an act like stooping, which, of course, raises the venous pressure and expands the brain, causes a momentary qualm of dizziness and headache. Along such lines as these are to be explained the intermissions in the symptoms of unresolved contusions without improvement in the actual condition itself, and the mode of action of the various causes that precipitate the attacks.

Mechanism by which Cerebral Contusions are Produced.

We have spoken of the complete rigidity of the skull in relation to forces of physiological magnitude. We must now turn to its entirely different behaviour in relation to forces of another order. It seems natural to think of the skull as a very strong shield and enclosure of the brain, which yields only to extreme violence, and only when it is broken. The natural result of this attitude is to put fractures of the skull into a position of primary importance, and to treat injuries of the brain as mere complications of them. This conception is, of course, nowadays quite exploded, and I refer to it merely that by calling attention to the relative pathological insignificance of fractures of the skull, I may give emphasis to the importance of head injury without fracture.

In relation to forces of adequate magnitude and kind, the skull behaves as a yielding and highly elastic structure, capable of undergoing considerable distortion and recovering its form without fracture. It is this property which permits of the occurrence of a whole range of important cerebral injuries altogether apart from fracture of the skull. It is out of the question that we should enter here upon a discussion of the many hypotheses that have been produced to explain the various intracranial effects of violence applied to the head. It would also be useless, since there can be no reasonable doubt that the essential primary mechanism in almost all cases is distortion of the skull.

The skull is apt to be distorted in two different ways. One is the result of a fall on the head when the cranium is compressed between the surface the patient lands on, and the weight of the body conveyed to the base by the spine. In this case a general deformation occurs diminishing the volume of the cranial cavity as a whole, and causing the acute compressive anæmia which is represented clinically by the nstantaneously oncoming paralytic phenomena known as concussion. The second type of distortion is a local deformation due to a localised blow on the head. Here of course there is no general squeezing of the brain and no concussion. In both forms of deformation the brain is apt to be bruised, and when this occurs without fracture of the skull and without other cerebral injury we may get the pure form of traumatic headache due to simple unresolved cerebral contusion. would again lay the strongest possible stress on the act that these conditions can be set up by comparaively trivial-looking accidents, and that once estabished they are distressing and seriously disabling afflictions.

TREATMENT OF TRAUMATIC HEADACHE.

The headache of unresolved cerebral contusion is ortunately sometimes preventable, and almost always urable. Prevention is possible chiefly in relation to he widespread but slight degrees of contusion ssociated with general deformation of the skull and oncussion. It is to be attempted by the strict pplication of the old clinical maxim that every case of concussion must be treated by a definite period of rest in bed, and the very slow and cautious resumption of active life. The duration of such precautionary treatment may, to some extent, be regulated by the presumptive severity of the contusion in the given case. The best measures of this are the extent of the patient's loss of memory for the period of the accident, and the intensity of the so-called phenomena of reaction that have followed the concussion. Supposing headaches to have developed in spite of proper preventive treatment, they may be dealt with by another and lengthened period of rest in bed. This failing, a moderate decompressive opening in the skull and dura is practically certain of success. It should be made at the place of election low down in the right temporal fossa under the muscle. Localised contusion, as it has to be more intense to produce similar symptoms, is less amenable to precautionary treatment by rest, and is more likely to call for primary operative treatment. This consists in making an opening in the skull and dura over the contused region, so that the latter may be released from pressure, its normal circulation re-established, and resolution occur. There are certain cases in which the occurrence of a serious amount of local cerebral contusion may be assumed to be present from the very nature of the injury. Such an injury, for example, is a glancing blow by a rifle bullet. Here, though the skull seems to be intact, and even the scalp is only grazed, cerebral contusion may be assumed to be present, and operation advised, even in the absence of any early symptoms.

We have now reviewed a limited but very definite and compact section of the great subject of head injuries. This review has, I hope, illustrated to some extent an important branch of cerebral pathology—the functional relations of the skull and brain—and at the same time remained in close contact with the practical realities of medical work.

VULNERABILITY OF THE BRAIN IN THE INDIVIDUAL AND IN THE RACE.

We may now ask whether this same series of facts and inferences is capable of yielding any idea of more general scope, and capable of application outside the technicalities of medicine. There is one suggestion, at least, conveyed by these facts, which, to my mind, tempts further inquiry, and that is, that as compared with what one might perhaps have expected, the brain is shown to be a relatively vulnerable organ, and that this vulnerability is due to the failure of the protective function of the skull in face of even comparatively moderate violence of certain kinds.

That in very early life the brain has a high vulnerability is no unfamiliar idea. We owe our knowledge of the fact largely to the well-known researches of our President, published, as I may perhaps remind you, no less than 33 years ago. He showed in a long series of examinations of still-born infants that in somewhere in the neighbourhood of half the subjects there was definite intracranial injury in the nature of hæmorrhage and bruising.[1] It is a good example of the essential unity of all branches of medicine that is upheld in the very structure of our Society, that the student of cerebral pathology can still turn gratefully to this classical paper in obstetrics. The similar, though doubtless less pronounced, vulnerability that exists in the adult is revealed to us not so much by direct evidence, as through the unique obstacle to the resolution of minor traumatic lesions that is produced by the bony encapsulation of the brain. Any extended consideration of this vulnerability of the adult brain brings to light the probability that it is in some special degree a consequence of the characters of the modern European skull. It is more or less common and accepted knowledge that, for example, the African races are, on the whole, much less susceptible to the minor traumatic lesions of the brain than are Europeans. Blows on the head that would paralyse the latter are sustained with comparative indifference by the former, and it is obvious that this variation in susceptibility depends on a difference in the resistiveness of the skull in the two races. We thus find that our subject, in the first instance purely medical, has led us, as we suggested it might, into matters of a more general interest, and that we are now faced by questions less medical than anthropological. It is necessary, therefore, though of course, with every precaution of diffidence, to inquire whether it is possible for medicine to contribute in any useful way towards the solution of problems specifically those of anthropology. In the study of the evolution of man and the differentiation of the various races, the anthropologist is to a great extent limited to anatomical considerations of form and structure, and to him what may broadly be called functional considerations, though admittedly to be desired, are most often not available. The student of medicine, on the other hand, is primarily interested in function, and makes use of structural observations only in so far as they explain function. The tendency of medicine is more and more to lay stress on function, and to give emphasis to the principle that, at any rate in the individual, disturbance of structure lags far behind disturbance of function, while the study of function is a far more delicate method of differentiating the states of living matter than is the study of structure. The two races I have mentioned, African and European, afford incidentally a very good illustration of the difficulties of the anthropologist as seen by the student of medicine. We have full accounts of the differences of form presented by the two races, we learn that while in detail they are not very great, they are in sum at least, considerable; but we get nothing in the way of a rational explanation of the immense functional difference that is represented by the fact that while one race is capable of producing a continuously evolving culture, the other remains in this respect completely stationary both in its native habitat and in transplantation. It does not seem that there are differences of cranial capacity or convolutional complexity marked or constant enough to be correlated with this great functional disparity; it would appear, therefore, that the problem is insoluble by anatomical methods, or that the anthropologist must tend to minimise the significance of the functional difference that, from our point of view, is so great.

---

[1] H. R. Spencer: On Visceral Hæmorrhages in Still-born Children, Trans. Obst. Soc., 1891.

We have seen that the European skull does not protect the enclosed brain from injury so efficiently as does the African skull. This must be because the latter is the stronger, and more rigid. From the anatomical point of view, this superior strength is evidently not very striking, since, as far as I know, it has attracted but little attention and led to no attempt being made to measure it. From the functional and medical point of view the superior strength of the African skull is at once obvious, and is plainly a very important racial character. The superior rigidity and massiveness that in the African are not anatomically very obvious, at once become unmistakable in the skulls of prehistoric and admittedly more primitive races, such as Neanderthal man, and Piltdown man, in which the massiveness of the cranium has impressed all observers. The relative slightness and flexibility of the European cranium is, then, a leading character of the race, and since, as we have already shown, it brings with it gross functional disadvantages in the resistance of injury, we may assume that it has some deep and real significance in compensation. That is to say, it "paid" the European, so to speak, to develop a type of cranium which put him at a serious physical disadvantage in contest with his primitive competitors and even with contemporary races of to-day; what can have been the "price" he got in return that prevented the transaction from being the bad bargain it so manifestly might have been, but was not?

EVOLUTION OF THE SKULL IN RELATION TO FUNCTION.

If we survey the evolution of the skull in a very broad and general way, it is plain enough to see that the factors that destined the anterior ganglion of the primitive animal to be the brain of the higher vertebrate, rendered it inevitable that the part of the skeleton that should ultimately furnish the capsule of the brain should be from the first involved with other functions, such, for example, as nutrition and respiration. The cranium, therefore, in addition to acting as the capsule of the brain, has had to take part in forming the nasal respiratory apparatus, the apparatus of mastication, and in providing extensive areas of attachment for the trunk muscles. It cannot but be supposed that these various functions have interacted on one another, and that the interaction has compromised the perfection of the individual function. Thus, for example, the more the cranium had to provide for the attachment of masticatory and neck muscles, the less fully and sensitively could it fulfil its function of cranial capsule, and allow the smaller individual variations of the brain to have their fullest and least restricted scope. It is interesting to notice that when the skull was involved in yet another function—providing attachment for horns—cerebral development seems to have been abruptly checked. In man, even of the most primitive types, the liberation of the cranium from accessory functions took a large step forward but long remained imperfect. In Neanderthal man the brain was not uncommonly as large as, or even a good deal larger than, it is in the average European, and yet this great brain was enclosed, and perhaps we may say imprisoned, in a hugely massive cranium that gave attachment to very extensive masticatory muscles, and was encroached upon posteriorly by neck muscles far more widely than is the skull of any other race. It cannot be supposed that in such a veritable fortress of bone the brain was as free to develop its potentiality for small individual variations as is a brain less formidably enwalled.

It seems probable that a progressive civilisation—that is to say, a cultural evolution which, though perhaps aimless, is continuous—depends less on the appearance of unusually able and original individuals in the race than on the free production of quite small variations round the mean. Contributions of originality, in order to be continuously and securely built into the fabric of a culture without disturbance, should be individually small or even infinitesimal, and it is this condition that appears to be realised when the brain is free to develop its minor variability, and to be lacking when the brain is subject to the slight restricting effect of a cranium loaded with accessory functions. There seems, therefore, a certain plausibility in the hypothesis that the secret of the modern European type—and I use that term, of course, in the sense of the anthropologist rather than in that of the historian—lies in the capsular function of the cranium having acquired in that type for the first time a definitive supremacy over the accessory functions. If it is this *supremacy* of the one function that was the original variation that constituted the European type and is an inherited character in it, then it must be capable of producing progressive effects, and we ought actually to be able to detect evidence that the accessory functions of the cranium are undergoing decay. The relative slightness and low rigidity of the European skull in comparison with the African is possibly a manifestation of this process, and is probably progressive. European skulls are without any doubt remarkably variable in density and thickness, as anyone with operative experience can testify, and such variability is, at any rate, highly suggestive.

It is generally recognised that the masticatory apparatus of modern man is undergoing atrophic changes, and at no very slow rate. This is, of course, most clearly seen in the teeth, in which the process of suppression of the molars from behind forward has gone so far that already we may almost regard two fully erupted molars on each side as more properly representing the normal than three. It is to be remembered that the molars are still physiologically the most valuable of the teeth, and those the loss of which produces the most serious effects. On this account alone, and apart from far more serious theoretical difficulties, it seems impossible to assign any value in the explanation of their suppression to disuse. A more trustworthy line of speculation is suggested by the fact that it is the anterior teeth which seem least to show the tendency towards suppression, those teeth, that is to say, which are actuated by the masseter muscle, which is not directly connected with the cranium. On the other hand, the teeth which do show the tendency to suppression are those associated in function with the temporal muscle which arises directly from the cranial wall. The cranium is, so to say, throwing off the remnants of its masticatory function, and the temporal molar group is consequently tending to disappear.

No one could acknowledge more readily than I do the speculative nature of these suggestions; at the same time it may perhaps fairly be said that they bring into some kind of relation a body of facts that possibly has not been viewed in connexion before. However that may be, I would rather claim my justification for troubling you with them in the attempt to show that even a strictly technical subject and one of everyday practical importance to the medical man, cannot exist in isolation, but tends inevitably to throw out implications of wider and wider reach, and of more and more general significance.

Goulstonian Lectures

ON SOME

WASTING DISORDERS OF EARLY INFANCY.

Delivered before the Royal College of Physicians of London

BY LEONARD G. PARSONS, M.D.,
F.R.C.P. LOND.,
ASSISTANT PHYSICIAN, GENERAL HOSPITAL; PHYSICIAN TO BIRMINGHAM AND MIDLAND HOSPITAL FOR SICK CHILDREN; PHYSICIAN TO THE MUNICIPAL INFANTS HOSPITAL, BIRMINGHAM.

LECTURE III.[1]

Delivered on April 1st, 1924.

IN this final lecture I propose first to deal with sulphæmoglobinæmia. I know of no instances in the literature of the occurrence of sulphæmoglobinæmia in infancy. I would therefore like to give some details of an infant who, whilst under treatment for atrophy, developed sulphæmoglobinæmia.

A child, 3 weeks old on admission to hospital, weighed 8 lb. 2 oz., and had a history of projectile vomiting. There was no evidence of pyloric stenosis; the child was of normal colour and with no physical sign of disease, but soon after admission diarrhœa developed, accompanied by a slight degree of fever, and there was a continuous fall in weight to 5½ lb. The stools during the first part of this period were very green, and then it was noted that they took on a bluish appearance, were, indeed, almost Cambridge blue. The stools were examined for the presence of *Bacillus pyocyaneus* with negative results. A few days later the sister of the ward was struck by the bad colour of the baby; he was very blue and she therefore administered oxygen, but reported that this administration made no difference to the colour. On questioning the sister, she told me that the child had been blue for short periods during the previous two or three days. For the following three weeks the child was constantly blue, the colour gradually fading during the third week. The blueness was apparently more marked at night, but this, I think, was probably due to artificial lighting. The colour was very striking, being almost of a leaden hue; it affected the skin generally, but was most marked in the extremities and mucous membranes. Blood removed for the purpose of spectroscopic examination was chocolate in colour. The spectrum showed a band in the red to the left of the D line, which remained after shaking the blood with ammonium sulphide, thus differentiating it from the band of methæmoglobin. It has been stated that the condition is probably related to the presence of a nitrite-producing bacillus in the saliva, and that nitrites are present in the urine and saliva.[1] I therefore examined both the secretions (by Gries and Gries Ilosvay tests) for nitrites, but in neither secretion was I able to find any trace of them. The urine was examined directly after it had been passed, but these investigations were not carried out when the colour was most intense. Dr. H. G. M. Henry, bacteriologist to the City of Birmingham, very kindly examined both the swab from the buccal cavity and the stools for the presence of nitroso-bacilli, and again with negative results. It is interesting to observe that from the time that the notes state "colour is apparently almost normal," the increase in weight of the child was almost continuous from 5 lb. 8 oz. to 10 lb. 3 oz., when he was discharged from hospital. During this time there was never any return of the blue coloration, and since the child's discharge from hospital, now a year ago, his condition and progress have been normal. During the early period of the child's gain in weight, and after receiving a proprietary food for seven days, œdema of face, hands, and feet developed. The œdema lasted four days, gradually disappearing. The diet was unaltered. The œdema was of the type described by Bloch as dystrophia amylogenetica, although this child had not received large quantities of carbohydrates, the amount of sugar in the food in the dilution used being about 8 per cent. I should also like to add that although the case was under my charge, the diagnosis was suggested to me by my colleague Dr. Laurence Ball.

PYLOROSPASM.

The occurrence of a definite clinical syndrome, pylorospasm, has been denied by many authorities, whilst by others it has been regarded as a stage in the development of pyloric stenosis. It is generally accepted that a super-added pyloric spasm is the cause of some of the symptoms of pyloric stenosis, but that spasm alone can cause stenosis is not generally accepted. Clinically, it appears to me that it is quite possible to separate pyloric spasm from stenosis, and I feel convinced that such a condition does occur, and that it frequently results in the production of simple atrophy, but never results in pyloric stenosis. The latter statement is, of course, difficult to prove. I can only say that I have never seen a case of pyloric spasm become one of pyloric stenosis.

Pylorospasm probably can occur throughout the whole period of the time during which the child is fed on a fluid diet, but the commonest age is about three months. The following history is usually given: The baby was a normal infant and thrived well at first, subsequently vomiting occurred and the child lost weight. Throughout the illness vomiting was frequent and often severe, and constipation or diarrhœa was present. On examination the degree of wasting is noticed to be less than usually occurs in a case of pyloric stenosis of the same age and duration of symptoms. After feeding the outline of the stomach can be seen, and very often feeble peristaltic waves. The usual experience is that when examining these children for peristalsis, "they flatter only to deceive"; what seems to be the beginning of a well-marked peristaltic wave appears under the left costal margin and rectus muscle, but suddenly when the wave seems to be going to move across the abdomen the child wriggles, contracts one side or segment of the abdomen, and when he becomes quiet again there is not any wave to be seen. At other times quite well-marked peristaltic waves occur—so marked that I have had two cases operated upon as cases of pyloric stenosis.

A pyloric tumour cannot be felt. I am aware that a contrary view is held, particularly by American writers, who state that in severe cases a pyloric tumour is palpable; that in certain cases it can be felt to contract and relax from time to time, and that this alteration in consistence serves to separate the case from pyloric stenosis in which such variation is never observed. In my opinion, if a tumour can be felt, the condition is one of stenosis and not spasm. Alteration in consistence of the tumour as determined by palpation does occur in stenosis. Indeed, at times the tumour appears to fade away, because in diastole the stomach falls over and masks it, whereas in systole the tumour is uncovered. This was first pointed out by Miller and Wilcox.[2] One other point is, I think, strong evidence against the palpation of a tumour in pyloric spasm—namely, that the surgeon, when operating and directly palpating the pylorus, has no hesitation in saying whether a case is pyloric stenosis or not. If a tumour were present in spasm he would not be able to form such a clearly cut opinion.

---

[1] In the second Goulstonian Lecture the word *decinormal* (THE LANCET, April 19th, p. 798, col. 1, line 47) should read *2 5 normal.*

Pain of a colicky nature is not an uncommon symptom in contra-distinction to stenosis, in which it is rarely observed. The children are often unduly miserable and fretful. The tongue is clean and anorexia is frequently observed. In stenosis, except perhaps in the terminal stages of the condition, anorexia does not, in my experience, occur.

Constipation does not reach the severe grade of pyloric stenosis, and not infrequently it is replaced by diarrhœa, or the stools may be normal in number. Vomiting may be severe and explosive in type, approaching the projectile variety, but again the severe projectile vomit seen in stenosis does not occur; neither is there residual vomiting. The vomit does not contain mucin. Very often after the patient is admitted to hospital vomiting is not marked; this is probably due to the fact that the patient responds quickly to treatment. A recognition of the significance of this fact would have prevented my mistake in having two cases operated upon as stenosis, to which I have already referred, and in which the diagnosis was made on the marked peristalsis. In these cases vomiting had not occurred during their stay in hospital, although there was a history of its occurrence prior to admission.

X Ray Diagnosis of Pylorospasm.

Radiographic examination may be helpful in arriving at a correct diagnosis of pylorospasm, but it may lead one astray unless observations are made for at least three hours after feeding. The stomach does not show dilatation as in stenosis, and peristalsis is usually much less marked. Dr. C. G. Teall, the radiographer to the Children's Hospital, Birmingham, informs me that he thinks it is possible to differentiate between stenosis and spasm. In stenosis, although there is delayed emptying of the stomach, yet if food does pass through the pylorus it does so more or less regularly over the period observed. On the other hand, the X ray appearance of the stomach in spasm may suggest a stenosis in plates taken one hour and two hours after food, but in a plate taken three hours afterwards practically all the meal will be seen to have passed through the pylorus. Of course, if food is retained in the stomach for long periods, four hours or more, the condition is certainly stenosis.

That a wrong deduction can be drawn from radiography unless observations are made for at least three hours after feeding is shown by one of our first radiographic examinations of pylorospasm. This case clinically was a case of spasm and not stenosis, but the X ray finding was one of pyloric stenosis, because practically all the food was retained in the stomach at the end of two hours. This child came to autopsy, and the clinical view that stenosis was not present was substantiated. If this case had been examined three hours after feeding, in all probability the X ray finding would have been a different one.

Under treatment the majority of the cases do well; the vomiting stops, due to a relaxation of the spasm, and the child begins to gain weight. Some cases develop into severe atrophy and die from that condition. In these cases I think death is due to atrophy and not to spasm, and that even in severe cases the spasm can be overcome, but the atrophy cannot be cured. I do not believe that operation is ever indicated, although it is recommended for the severest cases by some writers (Talbot and Morse).[3]

From what has been said it will be apparent that it is difficult to separate cases of spasm from pyloric stenosis; indeed, the statistics of recovery in pyloric stenosis under medical treatment have been subjected to the criticism that many of the cases regarded as mild stenosis were in reality pylorospasm. As in all forms of simple atrophy, pylorospasm rarely occurs in breast-fed babies; the spasm may be a reflex one due to the presence in the stomach of large curds from cows' milk feeding. Miller and Wilcox[2] thought the condition was due to hyperacidity, because they always found a hyperchlorhydria in examining stomach contents withdrawn one hour after a test-meal. Increased hydrochloric acid is, however, not always found, and when present is quite possibly the result and not the cause of the spasm, although in some cases the beneficial effect of adding sodium bicarbonate to the milk cannot be doubted. The observation of Spencer, Meyer, Rehfuss, and Hawk,[4] that a 1 per cent. solution of sodium bicarbonate hastens the emptying of the normal stomach, shows that this beneficial effect may not be due to a simple neutralisation of excess of acid.

It has been stated that pylorospasm is a manifestation of the hypertonus of the hypertonic infant, but it is frequently seen without any other evidence of hypertonia. In a recent paper White[5] states that this condition would be more correctly called gastro-enterospasm, because when there is pylorospasm there is also, he asserts, enterospasm. He further states that "gastro-enterospasm is a manifestation of autonomic imbalance" or vagotonia. The nervous mechanism controlling gastric and intestinal peristalsis is normally kept in a state of balance by the bulbar autonomic division of the parasympathetic, and its opponent the sympathetic. This mechanism is probably only a controlling one, for it has been shown by several observers that gastric peristalsis and the pyloric reflex have remained normal after both splanchnics and also both vagi below the diaphragm have been cut (Cannon). Stimulation of the vagus produces inhibition of cardiac sphincter and contraction of the pyloric sphincter. The chief evidence on which White bases his theory is the beneficial results he has achieved by the use of atropine, "which is a specific for vagogenic gastro-enterospasm." Based on Langley's work, he suggests that an excessive production of cholin with its accompanying stimulation of vagus may be the cause of the autonomic imbalance.

Treatment of Pylorospasm.

In the treatment of pylorospasm breast milk should be given if possible, but, unfortunately, it is rarely available. In the absence of breast milk I have obtained the best results by lavage of the stomach with bicarbonate of soda (1 per cent.) daily, and the giving of an ordinary milk mixture. It has been found useful at times to give citrated milk with the resulting smaller curd. I have also frequently added to the milk bicarbonate of soda (½ to 1 gr. per oz. of milk), and in those cases where hyperacidity occurs the results are good. I have tried the thick feeding of Sauer in a few cases, but without much success, although in one case it produced brilliant results after all the other methods, including the giving of atropine, had failed. On physiological principles skim milk has been tried, but, except when diarrhœa was present, with no better result than ordinary milk mixtures. Atropine, on the whole, has been disappointing, but occasionally has appeared to be of value. It has been given as belladonna or atropine before, with, or immediately after, food. Recently White's method of giving 1/1000 gr. 15 minutes before feeding, and increasing the dose if necessary, has been tried. He states that "definite flushing" is evidence of sufficient dosage, but I found in one case marked intestinal distension—so marked that it was necessary to stop the atropine—without any sign of flushing.

The consideration of pyloric spasm leads naturally to a main subdivision of my subject:—

INFANTILE PYLORIC STENOSIS.

This is a subject on which much, very much, has been written, but which has a curious fascination for the great majority of those interested in the diseases of childhood, and which still presents many controversial points for investigation and discussion. It is to some of these points, and to the question of treatment in particular, that I wish to draw attention. The history of the discovery of this disease is now well known, and I do not intend to enter into any extensive review of the literature. I would, however, like to point out that although the credit for having reported the earliest instance of the condition is given to one who, as Hutchison humorously puts it, bore the prophetic name of Hezekiah Beadsley, yet probably the first description in the literature was actually given by an English physician, George Armstrong, in his "Account of the Diseases most Incident to Children," published in the year 1777. His description is worth putting on record again.

> "In a child about 3 weeks old that died of the watery gripes, and which I opened some time since, I found most of the stomach towards the upper orifice and almost the whole fundus in the same tender state with that of the child just now mentioned" (this is a reference to what were obviously post-mortem changes in the stomach). "But towards the pylorus the structure was firm enough, as likewise that of the intestines both small and great. The stomach was quite distended with curdled milk and victuals with which the nurse had crammed the child, mixed likewise with some of the chalk julep, but the whole intestines were remarkably empty. There was no morbid appearances to be observed anywhere but in the stomach, and this *viscus* being so full, while the intestines were almost empty, it looked as if the disease had been chiefly owing to a spasm in the *pylorus*, which prevented the contents of the stomach from passing into the *duodenum*. Perhaps cases of this kind are more frequent than is commonly imagined."

The wide recognition of the disease, not only in the British Isles but all over the world, is largely due to the work of John Thomson and Still. The distinction of first demonstrating a case in London is due to Cautley, and also to him is due the credit for persistently advocating surgical intervention when such treatment was very unpopular. Of surgeons who have contributed considerably to our knowledge and successful treatment of this disease I would mention Stiles, Burghard, Nicol, Dent, and more recently Rammstedt, of Münster, Downes, of New York, Tyrrell Gray, Seymour Barling, and Higgins.

Ætiology of Infantile Pyloric Stenosis.

The view of the ætiology of the condition that commends itself to me is the one which regards the hypertrophy as a congenital abnormality, and the onset of symptoms as due to either a superadded spasm, completing the incomplete block, or to swelling of the mucous membrane of the pyloric canal producing the same result; or to a combination of both these factors. I have already stated that in my opinion pyloric spasm does not lead to pyloric stenosis.

I would quote two cases seen recently which may have some bearing on the ætiology. At the autopsy on a case of pyloric stenosis, in addition to the hypertrophied sphincter, there were seen in the descending colon three contracted segments of bowel, quite short in length and separated from each other by bowel having a normal lumen. On microscoping the bowel it was found that in these contracted portions the circular muscle coat was much thicker than in the uncontracted portions. This hypertrophy was a real and not an apparent one, due to the contraction of the circular muscle coat. The other case was one under the care of my colleague Dr. Ball. This infant was admitted to hospital as a possible case of pyloric stenosis. The history given by the mother was to the effect that the child was normal for the first month, after which time he began to have frequent vomiting, "pumping his food up just when it went down." His bowels had always been constipated and he had wasted considerably. After admission to hospital it was noticed that vomiting occurred directly after food was swallowed, actually at the time the baby was taking the bottle; there was absence of visible peristalsis and a pyloric tumour could not be palpated. An X ray examination showed a picture that was regarded as typical of achalasia of the cardia. At the autopsy it was found that the œsophageal wall was greatly thickened for about 1 inch above the cardiac orifice, and that this thickening was due to an enormous hypertrophy of the circular muscle coat. The mucous membrane of the œsophagus was normal, and above the obstruction the œsophagus was dilated. The pyloric sphincter was normal. These cases seem to show that hypertrophy, limited chiefly to the circular muscular coat, may occur in parts of the alimentary tract other than the pylorus.

Development of Pyloric Musculature.

Prof. J. C. Brash, professor of anatomy in the University of Birmingham, has very kindly undertaken some researches in the development of the pyloric musculature with a view to determining whether this would throw any light on the occurrence of the pyloric hypertrophy. Prof. Brash has placed his results and reconstruction models at my disposal, and I am greatly indebted to him for his kindness.

The following stages in the development of the stomach musculature from Keibel and Mall[6] are interesting. In a 10 mm. embryo—i.e., aged 6 weeks—the stomach wall consists of three layers of entodermal epithelium, mesenchyme, and peritoneal epithelium. In a 16 mm. embryo (aged 7 weeks) there is a condensed zone of mesenchyme which represents the future circular layer; this is best defined along the lesser curvature. In a 22·8 mm. embryo (age 7–8 weeks) the circular muscle is complete and shows a slight thickening towards the pylorus. In a 37 mm. embryo (age 9–10 weeks) a prolonged gradual thickening of this layer, followed by an abrupt thinning at the duodenum, is distinct now and in all later stages. In a 240 mm. embryo (age 27–28 weeks) an outer longitudinal layer is distinct in the pyloric part of the stomach, and it becomes thicker towards the duodenum.

The reconstruction models are those of the stomach and duodenum of a 15 mm. human embryo—i.e., less than 7 weeks old—and a 20 mm. cat embryo, and the following are Prof. Brash's findings and comments. The form of the stomach is clearly defined in both. The differentiation of the muscular coat (primary "circular" layer only) is clear in both, especially so in the cat, which is in a considerably more advanced stage of development. There are thickenings of the muscular coat at all bends, notably in the human embryo at the well-marked incisura angularis, and in the cat embryo at the pylorus. In the human embryo the edge of the "pyloric ring" is situated at the distal part of the bend to the duodenum, whereas in the cat embryo it is at the proximal part of the same bend. It is an interesting question whether the bend to the duodenum has anything to do with the thickening of the circular coat of the pyloric canal of the stomach as far as this part, or whether the bend is the result of the sudden transition from thick stomach to thin duodenum. The latter is the more probable.

In the cat the thickening at the pylorus is so marked that the mucous coat is crumpled and nearly fills the lumen, allowing only a pin to pass through in the model at 50 magnifications. The transition to the thin coat of the duodenum is very abrupt. Differentiation is not nearly so advanced in this region in the human embryo. The apparent thickening of the mucosa at the pylorus is, however, not to be taken as absolute evidence of a growth process. It may be due to muscular contraction produced by the preservation of the embryo. There are longitudinal folds of the mucosa in the body of the stomach in this specimen, and it is stated (Toldt) that these have been seen to be produced by muscular contractions in the freshly opened stomachs of embryonic cats.

It appears that the differentiation of the circular muscle coat and the formation of the pylorus take place so early that it is impossible to come to any conclusion as to whether the actual process of the formation has anything to do with hypertrophic stenosis of the pylorus. Assuming that the appearance of the mucosa at the pylorus in the cat is due to the growth of muscle, it seems probable that the pyloric muscle develops as far as it can at an early stage and practically obliterates the lumen—i.e., the conditions in the embryo are identical with those found in cases of pyloric stenosis at operation, or found post mortem in fatal unoperated cases. If normal conditions are produced at a later stage of development by differential growth of the muscles and the mucosa, then the cause of pyloric stenosis, assuming it to be a congenital abnormality, is likely to be found in the conditions that control this differential growth. Thus pyloric stenosis may be the persistence of a normal stage in the embryo.

The similarity between the condition found by Prof. Brash in the embryo of the cat and the condition of the pylorus at operation is, in my opinion, very striking and suggestive.

The theory that the pyloric stenosis may be due to hyperadrenalism in the mother[7] cannot, I think, be held in view of the published investigations of Barling and myself.[8] In this connexion it may be of interest to note that I have washed out the stomach of a case of pyloric stenosis (before operation) with adrenalin hydrochloride without any increase of symptoms; indeed, the child improved under the treatment, and I have also given the drug subcutaneously without any ill-effect.

Diagnosis.

In my remarks on pylorospasm I have stated that it is difficult to diagnose pyloric stenosis from pyloric spasm. In the diagnosis of pyloric stenosis the most important points are the history of the development of the illness, the presence of persistent and projectile vomiting, constipation, progressive wasting, visible peristalsis, and palpation of a pyloric tumour. Peristalsis, it is true, occurs in pylorospasm, but it is usually of much milder degree, and very rarely indeed is it the very obvious slow type so characteristic of stenosis. If with this type of peristalsis there are the symptoms detailed above, and if the presence of persistent and projectile vomiting, often very large in amount, can be verified, then, I think, the diagnosis of pyloric stenosis is justified, and the palpation of the tumour is unnecessary. If, however, the peristalsis is less pronounced, and it is difficult to be certain of the character of the vomit, palpation of the tumour is absolutely essential to the making of the diagnosis. The presence of a tumour is certain evidence of pyloric stenosis.

For a diagnosis of pyloric stenosis investigations other than the ordinary clinical examinations are unnecessary, but chemical examination of gastric contents and radiographic examination may both yield useful confirmatory evidence, and also give important indications as to the size of the stomach and the degree of stenosis. To the results obtained from the first of these methods I have already referred, and I would only add here that, although in my experience blood has occasionally been present, bile has never been found in the stomach contents or in the vomit. Dr. John Thomson, however, tells me he has seen bile in the vomit in three or four cases, and Still[9] says that he has also seen it on rare occasions. During the last few months there have been admitted to the Children's Hospital, Birmingham, two cases showing symptoms somewhat resembling pyloric stenosis, but which eventually proved to be cases of congenital duodenal ileus. In both cases bile was present in the vomit to a marked degree, and one of the cases was also definitely jaundiced.

Radiographic Investigation.

In the most recent contribution to the literature on the treatment of pyloric stenosis is the statement that the writers "do not as a rule give bismuth meals, because our experience has been that they may do harm to the infant who has no reserve power, and that they do not in ordinary cases tell us more than we can discover by clinical examination."[10] This statement is one with which I cannot entirely agree. Radiographic examinations have been carried out in a large number of my cases, and the condition of the patient has presented many grades from comparative healthiness to great feebleness, but I have not yet convinced myself that the examination has ever done any harm. At the same time, it is perhaps fair to say that in one case the ward sister informed me that in her opinion the condition of the child became worse owing to the long period (3 hours) it was kept without food; I should also say that although I have had moribund cases operated upon, I have not had them radiographed. As I have stated, radiography is unnecessary for a diagnosis, but even in ordinary cases it will tell us more than we can discover by clinical examination, unless under the head of clinical examination is included the removal of stomach contents, as for a fractional test-meal. Radiography gives us accurate information concerning the size of the stomach and its rate of emptying. As a matter of fact, it is not necessary to give the baby a barium meal to estimate the size of the stomach; indeed, Dr. Teall tells me that in his opinion possibly a more correct idea of the size is gained by not doing so.

It has been stated that X ray investigation will enable the physician to decide whether surgical or medical treatment should be carried out; my own practice is to have every case operated upon, so that I have not found radiography of any help from that standpoint, but from the point of view of investigation of the disease I think it is a very great help. For instance, radiography has shown that one of the advantages of the Rammstedt operation is that, for a time, a large part of the sphincter action is abolished, and that after a period of many weeks the normal sphincter control returns. One of the best examples of this effect on the sphincter is a case quoted in a previous paper.[8] A child, aged 11 weeks, before the operation showed on X ray examination very deep peristaltic waves, with retention of all the meal in the stomach for one hour, and of two-thirds of the meal for two hours. Three weeks later, after Rammstedt's operation had been performed, half the meal had left the stomach 15 minutes after feeding, and an hour later the stomach was almost empty. The same child, examined some five months later, and then aged 9 months, showed that emptying of the stomach contents had commenced 15 minutes after feeding, that one hour after feeding half, and two hours after feeding the whole of the meal had left the stomach.

When a barium meal is given it is usual to allow a three-hour interval between the preceding meal and the barium meal, and to allow another three hours interval before the succeeding. The meal used by Dr. Teall contains only a small amount (one drachm) of barium sulphate in an ounce of milk and an ounce of water; the child is spoon-fed, since this has been found to diminish the liability to sickness. Plates are usually taken immediately, one, two, and three hours after the meal, and another plate is taken on the succeeding day, the time after the meal being about 18–22 hours. The infant is photographed lying face downwards with the tube over the patient; this is done because of the difficulty of photographing the child in the upright position. The size of the stomach varies, of course, with the presence or absence of active peristalsis at the time of the taking of the photograph, but it is always seen to be enlarged. The largest stomach which I have seen occupied more than one-half of the abdominal cavity; this child was a girl, aged 3 months, from whom I removed, on washing out her stomach, more than 8 oz. of fluid containing a considerable amount of curd; the child made a complete recovery after operation.

The rate of emptying varies; in some cases the stomach commences to empty at once, and emptying goes on regularly all through the three hours. The amount passed through the pylorus may be considerable in this time, in one case as much as half the meal had passed, but this case was one undergoing medical treatment, and which was suffering from what proved to be a terminal diarrhœa. The cases in which a fair amount of food passes the pylorus might recover on medical treatment, and some physicians use this method of differentiating between cases which shall be treated medically and those which shall be treated surgically. I am convinced that it is a mistaken policy to treat these cases medically, because if so treated the majority eventually become worse and surgical treatment has then to be undertaken at a greater disadvantage than if the operation had been undertaken earlier. In other cases only relatively infinitesimal amounts of the meal pass the pylorus at the end of three or even four hours, and a considerable amount is found to be retained in the stomach wash-out at the end of 18–24 hours. Indeed, in one case a stomach wash-out showed the presence of barium 48 hours after the meal had been given.

Between these two extreme types occur the great majority of cases, which show the passage of only a small part of the meal through the pylorus at the end of three hours. I might perhaps add that X ray investigations agree with test-meal investigations in that the time required for the emptying of the stomach in atrophic infants varies very considerably. The stomach may be completely emptied at the end of one hour, or in cases of spasm, as previously indicated, practically none of the meal may have left the stomach at the end of two hours, although at the end of three hours the stomach may be quite empty.

The Rammstedt Operation.

When cases of pyloric stenosis were first recognised the type of peristalsis seen and post-mortem appearances of the tumour convinced many observers that surgery offered the only possible chance of cure. The results were not satisfactory and recoveries were reported by medical means, with the result that the pendulum of medical opinion swung to the opposite extreme. I was trained, and I am very proud to acknowledge it, in one of the strongholds of medical treatment—namely, Great Ormond-street Hospital. These methods of treatment I firmly believed in and carried them out in my own cases, but the results were very unsatisfactory, my recovery-rate being a very poor one. After the war period I determined to advise operative treatment, and since the appearance of a paper on the Rammstedt operation by Gray and Pirie,[7] every case of undoubted pyloric stenosis for which I have been responsible for treatment, without any selection whatever from more or less healthy children to moribund ones, has been operated upon. Every case has been operated upon because operation has given the child the best possible chance of recovery, and because this method is the only way to determine whether operative treatment is better than purely medical treatment. A certain number of cases during that time have refused operation, and these without exception terminated fatally. In a personal communication Holt tells me that he has come to hold the same view—namely, that Rammstedt's operation should be performed in every case—a view also shared by Poynton and stated by him in a recent paper.

The Rammstedt operation, consisting essentially as it does in dividing longitudinally the pyloric musculature and allowing the imprisoned intact mucous membrane to herniate through the opening, has been made the routine operation. The advantages of this operation are that it is easily and rapidly carried out, that it allows the food to pass by the natural channel over the duodenal mucous membrane, and that it does not interfere with the normal physiology as does a short-circuiting operation such as gastro-jejunostomy. The results of Rammstedt's operation reported in this country have been very encouraging, although no one has yet been able to produce figures that will compare with those of Burghard for forcible dilatation of the pylorus. The limitations of the latter operation are, however, well expressed by Still,[9] who says:—

> "In the past eight years Mr. Burghard has performed this operation on 46 of my private cases with only one death . . . . . This no doubt depends very largely on the particular operator, and cannot be taken as proving that the operation itself is as good as, or better than, the Rammstedt method. Indeed, in the hands of some surgeons it has had very little success."

Some surgeons might perhaps be rendered most surgeons. Of hospital cases, recorded by Still, that were operated upon by forcible dilatation, there were 12 recoveries and 16 deaths, figures which are easily surpassed by the Rammstedt operation.

At operation the pylorus is found to vary in length, thickness, colour, and consistency in different cases. The length of the tumour varies from about 3/8ths to 1½ inches. The reasons why these variations occur are not obvious. It is probable, as suggested by John Thomson, that whatever the condition of the pyloric sphincter at birth, its growth after birth is more rapid than normal, and that, as I have already indicated, imprisonment of the mucous membrane with the production of the typical symptoms occurs sooner or later. According to this view, in the acute cases, in which symptoms are early and severe, the pylorus should be relatively thicker and harder than in those cases in which the symptoms are milder and develop later. This, in practice, is frequently found to be the case.

Variations in Pyloric Tumours.

I am unable to account for the variations in length of the tumour, but some interesting observations by Wheelon and Thomas[11] on the relationship of the rhythmic activity of the pyloric sphincter to that of the antrum appear to throw some light on the variations in colour and consistency of the pyloric tumour. These observers carried out a series of observations, including naked-eye observations, examinations by X rays, and also the obtaining of graphic records by placing balloons in the antrum and in the pyloric canal. By the naked eye it was observed that peristaltic waves arose in the region of the pars media on the greater curve, and that the wave was greatest just in front of the vestibule where it often stopped; as a rule, however, slight wave contractions barely visible to the naked eye swept over the entire vestibule, to begin again as a powerful peristaltic wave which passed along the first part of the antrum. This progressed until finally the sphincter shut. At times the wave passed progressively from its origin over the vestibule and the first part of the antrum. When contracting, the force of the contraction was enough to cause marked anæmia of the part. This anæmia began at the gastric end of the antrum and gradually increased until the entire antrum was bloodless; at this point the sphincter began to lose colour, and this loss of colour persisted during the return of blood to the gastric portion of the antrum. All the methods used by these investigators showed that the antrum and pyloric sphincter are rhythmical in action—i.e., contractions and relaxations follow each other in a regular sequence. During the period of contraction of the antrum the antrum is pale, but the sphincter is relaxed and red, although commencing to contract and become pale just before the whole antrum is in contraction. After the whole antrum is in contraction, relaxation and reddening of the antrum begins, and the sphincter is most contracted and palest at the time of most marked relaxation of the antrum. These cycles occur at the rate of 3 to 5 per minute and are maintained for hours. Rhythmical motility was best obtained when the stomach contained food, but typical results were obtained from the recently emptied stomach.

Now the pylorus as seen at operation in pyloric stenosis is usually pale, hard, and avascular, but occasionally it is redder, softer, and vascular. The stomach at operation has usually been emptied by a previous stomach wash-out or by vomiting, and is also usually in the relaxed diastolic condition. In this condition, according to the observations of Wheelon and Thomas, the pylorus should show the pallor and firm contraction which is usually found.

I have already stated the reasons which in my opinion make Rammstedt's operation the rational proceeding in these cases, but mention might here be made of the support which such a method receives from the radiographic studies of Cole on gastric motility in man. He showed that the amount of contraction of the pylorus is proportional to the activity of gastric peristalsis—i.e., when gastric peristalsis is strong the sphincter is more tightly contracted. In pyloric stenosis there is, of course, very marked gastric peristalsis, and therefore the sphincter becomes more tightly contracted and the obstruction to passage of food greater. It would seem therefore, on theoretical grounds, that an operation like Rammstedt's operation, which eliminates for a time the sphincter action, is more likely to result in cure than treatment such as purely medical treatment, which does not eliminate the sphincter action.

After operation, visible peristalsis has been observed in a number of cases, it is less marked than before operation, and throughout the convalescence it becomes less and less obvious until finally it disappears. The wound in the pyloric wall soon becomes sealed with blood-clot and lymph. In a case examined 24 hours after operation the gap between the cut ends of the muscle was largely filled with lymph, the lymph being covered on the peritoneal side with a layer of blood-clot. This case also showed that even if only a thin strand of muscular tissue is left the mucous membrane will not herniate, and the condition is not relieved, for the operation was unsuccessful in this case, because the mucous membrane had been kept imprisoned by the merest shred of muscular tissue. After a time the lymph becomes organised and converted into young fibrous tissue. In a case examined 28 days after operation the herniation of the mucous membrane was well seen, and the gap between the cut ends of the muscle was filled with young fibrous tissue which was continuous on the one side with the peritoneal covering of the pylorus, and on the other side with the submucous fibrous tissue.

Post-operative Phenomena.

Full details of the operation and of pre-operative and post-operative treatment are unnecessary, as these have already been published. Successful results depend chiefly on careful attention to details. The margin between success and failure is a very narrow one, and without this careful attention on the part of the surgeon and physician failure will result. A most important factor in the post-operative treatment is the giving of initial small feeds, breast if possible, and their gradual increase. In my early cases I gave larger feeds, in amounts suggested in the paper by Gray and Pirie, but the great advantage of the small feed is that diarrhœa is less liable to occur, a complication that, if possible, should be prevented at all costs. It is interesting to note that although not adopting the same routine as that suggested by Barling and myself, Poynton, Higgins and Brydson have evolved a method of feeding in their cases which illustrates the same principle—i.e., initial small feeds cautiously increased. By this method of feeding the rapid increase in weight which occurs when larger feeds are given of course does not occur, but in many cases I am quite satisfied if the child for the first fortnight or so does not increase in weight, or only shows a small increase. Rapid increase in weight is the rule after 4 to 5 weeks, when the necessity for giving small feeds has passed away. I admit that this method of feeding is at variance with my recommendations when dealing with infantile atrophy, but I will explain my reasons for this inconsistency shortly.

Findlay[12] has very adversely criticised the giving of small feeds, and states that we continued unduly a starvation diet with fatal consequences; on the contrary, we feel convinced that by this diet we have cured cases which, treated otherwise, would have died. I have only seen one case in which the limitation of food might have been a factor in the fatal result; in that instance the child, who until a few hours prior to death had done extremely well, died from cerebral thrombosis (venous) on the twelfth day after operation; possibly if more fluid had been given subcutaneously or by rectum this would not have occurred.

The occurrence and explanation of certain post-operative phenomena is of great importance.

Diarrhœa.—All observers agree that this constitutes one of the greatest dangers to life during the post-operative period. Its occurrence is prevented to some extent by the giving of small meals as already stated, but even in cases so fed it may develop and prove a fatal complication. Like all atrophic children, these patients are liable to attacks of diarrhœa, but the liability appears to be greater than in simple atrophy. There is probably more than one cause of diarrhœa; one of the most important causes, it seems to me, is the diminished absorptive power of the intestine. The shrivelled, empty, atrophic appearance of the small intestine post mortem is well known, but there does not appear to be any anatomical change warranting the view that in pyloric stenosis the mucous membrane is atrophied. The diminished power of absorption is only for large amounts of material. The intestine has become accustomed to deal with a small amount of food only. If now, after operation, greatly increased amounts of food are allowed to pass into the intestine, it cannot absorb them, and diarrhœa results. In other words, a period of training of the intestine is necessary before the normal amount of food can be absorbed. As I have already pointed out, there is no evidence of deficiency of pancreatic lipase, and fat-splitting is normal. Probably the diarrhœa that occurs in cases treated medically can be explained wholly or in part in the same way, since in these cases diarrhœa is a late phenomenon, and associated with some relaxation of the pyloric block.

The evidence on which the foregoing statements are largely founded is based on clinical experience and from observations on the stools of patients taking small feeds only who were recovering after Rammstedt's operation. I have not given large feeds, nor have I examined diarrhœal stools, but from what has been said on the metabolism of fats, it will be remembered that when diarrhœa occurred fatty acids were present in excess in the stool. The presence of the fatty acid may give a greasy appearance to the stools, and this may be the explanation of why fat-splitting was supposed to be impaired in pyloric stenosis, and a pancreatic insufficiency inferred (Grey and Reynolds).[13]

Table I. shows two cases, observed for a considerable period after operation. The figures give the number of days on the metabolism bed, weight at the beginning and end of that period, average fat intake in grammes for 24 hours, the character and distribution of fat in stools, and percentage absorption. The first case shows that the power of absorption of fat increases as the period of time after operation lengthens, which may perhaps be accepted as supporting the view that the intestine is responding to its period of training. The other case does not show this so well, but all the experiments demonstrate that fat absorption under these conditions (small feeds and absence of diarrhœa) is good. In one experiment (R. 2), although the stools are semi-formed and absorption good, there is a high reading for free fatty acid which may indicate that the patient was on the verge of diarrhœa. For comparison with the results I have included figures showing the fat-splitting and the

distribution of fat in a case which was being treated medically by one of my colleagues.

As a result of these findings I do not now, in the absence of diarrhœa, use skimmed milk feeds; if, however, diarrhœa occurs, a weak fat mixture is substituted, and the fat content increased when the diarrhœa abates. The other causes of diarrhœa are probably the same as in infantile atrophy. Thus, in all probability, in artificially fed children of this type, there is an invasion of the upper intestinal tract and duodenum with *Bacillus coli*, and bacterial fermentation of sugar with the production of diarrhœa. Such an invasion may not occur prior to the operation because of the high acidity of the gastric juice in pyloric stenosis. I have not tried giving hydrochloric or citric acid milk in these cases, but theoretically it is worth a trial in infants about 3 months old. I do, however, frequently use a less fermentable sugar than cane sugar or dextrose—viz., dextrimaltose. The dextrimaltose should be kept in solid form and added to the milk. At one period recently I had three cases recovering from Rammstedt's operation, all of whom were being given dextrimaltose with their feed. To ensure greater accuracy in measurement the dextrimaltose was made up in solution. The same solution was used for some three or four days, when all these children became very ill; one vomited, the stools were loose; they all rapidly lost weight, one losing 15 oz. in a week. The fat in the food was cut down and solid dextrimaltose substituted for the solution, and they all made a good recovery. Finally, infective enteritis is just as likely to occur in pyloric stenosis as in infantile atrophy. The incidence of diarrhœa in infantile atrophy is considerable, although naturally the figures given by different writers vary. In the 100 cases of which I worked out the ætiology of atrophy, diarrhœa occurred in 27 after admission to hospital, and loose stools in an even larger number still.

Atrophy.—In a few cases after relief of the obstruction the child, already wasted, remains wasted and atrophic for weeks before beginning to put on weight satisfactorily. This group is not a very large one but it is a very definite one. The following is the most striking example that I have met with. A child, aged 11 weeks, was operated upon when its weight was 7 lb. 10 oz.; three weeks after operation he had gained 14 oz. (8 lb. 8 oz.); for the following three months his weight varied between 7 and 8 lb., and it was not until four months after operation that he began continuously to put on weight. The gain in weight, once it had commenced, was a rapid one. During this period of four months he was discharged from hospital and readmitted three times, each time with an attack of diarrhœa. I have seen altogether four of these cases and three of them recovered. These atrophic cases are also mentioned in the paper by Poynton and his colleagues, and apparently in the cases they saw the duration of symptoms before operation was a very long one; in my cases, however, this is not so, since the longest duration of symptoms was 28 days.

Vomiting.—In some cases this ceases directly the operation is performed, but it is not unusual for occasional vomits to occur for the first two or three days after operation, or even for as long as 14 days after the operation. The vomits are, however, usually small ones, and are not of the explosive and projectile type so characteristic of the cases prior to operation. The vomiting is probably largely due to the gastritis so usually associated with pyloric stenosis, and if it becomes troublesome can be treated by washing out the stomach with bicarbonate of soda (1 per cent.); one wash-out is usually sufficient to cure the condition. The probability of the occurrence of vomiting in any given case is greatly diminished by two procedures. First, careful pre-operative treatment, which includes a stomach wash-out once or twice daily for two days; and secondly, the use of nitrous oxide and oxygen as the anæsthetic. The use of this method of anæsthesia has another great advantage—i.e., the quick recovery of consciousness by the patient; the ward sisters have been greatly impressed by the superiority of this anæsthetic over others in this respect.

Post-operative Pyrexia.—This is common; indeed, there may be hyperpyrexia, a temperature of 107·8° F. (Poynton and others[10]) having been recorded; the highest temperature in my cases was 106°; this case died, but recovery has been recorded (Gray and Reynolds) with that degree of temperature. The pyrexia is usually of short duration, 24–48 hours, and all cases having hyperpyrexia developed the condition within 48 hours of operation. Some cases have shown pyrexia before operation, and after operation the degree of pyrexia may increase or diminish; fever is not to be regarded as a contra-indication for operation. It has been suggested that hyperpyrexia is due almost entirely to the anæsthetic (Gray and Reynolds), and that it does not occur with gas and oxygen anæsthesia. I have not seen hyperpyrexia after gas and oxygen, but pyrexia certainly occurs, the highest figure recorded being 103·8°. Personally, although so far I have not been able to produce a proof that will completely satisfy me, I think the explanation of the fever is to be sought for in the dehydration that occurs in these cases. The dehydration is a result of the disease. It is probably made somewhat worse by the operation, and considerably worse by the giving of subcutaneous saline if the solution used is a hypertonic one; in other words, the fever is essentially a "sugar and salt fever." In a few cases I have used continuous rectal hypotonic salines for 24-48 hours after operation. Pyrexia has been less frequent when this method has been used, and there has not been in any case any marked degree of pyrexia.

Comparison of Operative with Non-Operative Treatment.

In estimating the value of operative treatment in pyloric stenosis it must be remembered that medical treatment alone is a very lengthy process, often lasting three to four months or more, and that the issue is in doubt for a considerable part of that time. This naturally entails great anxiety on the part of the mother, and if she is feeding the child, may adversely affect the supply of milk. Operative treatment, on the other hand, if successful, usually offers complete recovery at the end of four weeks. This being so, it follows that even if operative treatment offers no better prospect of success than medical treatment, it is the more advisable procedure.

It is only fair in comparing the two forms of treatment to say that many cases are put down in statistics as deaths under medical treatment when they should really be classed as fatalities from lack of any form of treatment. Such cases come into hospital in an advanced atrophic condition, sometimes almost, if not quite, moribund, and in a condition when it is hopeless to expect them to receive any benefit from medical treatment. However, if Rammstedt's operation is performed on these cases a certain number of them will recover, and in assessing the values of the figures I give it should be remembered that there has been no selection of cases in any way whatsoever. Some of the patients have been absolutely *in extremis*; for instance, one had a convulsion just before the anæsthetic and died shortly after the operation was over. Every case which was not discharged from the hospital as cured has been included in the list of fatal cases, even when death was not the result of the operation, but due to intercurrent infection.

Most writers on the subject of treatment of pyloric stenosis have stressed the different results obtained in hospital and private practice. Indeed, my previously published results have been criticised on the grounds that these two groups were not considered separately, and the statement has been made that "so different are the results in these two fields of practice by either method of treatment, that to combine them in any statistical investigation . . . must necessarily vitiate the conclusions" (Findlay[12]). To avoid that criticism in the present lecture I have separated my cases into private and hospital patients. It will be noticed that I have seen very few cases in private which have received medical treatment, and all of these died. The number may be too small to be of any value; I have, however, had 11 private cases operated upon by Rammstedt's method with recovery in every case. It should be made clear that, although these were private cases, they were, with one exception, all treated in hospital. They became private patients simply because they were nursed in a private ward and because they paid nursing fees to the hospital, and in some cases, of course, medical fees as well. It is interesting to note that two cases which, because of lack of accommodation in the public wards, were treated in this ward proved fatal. I think therefore that the criticism quoted cannot be accepted as a valid criticism of my results.

The results I have obtained by medical treatment make very sorry reading, but bad as they are, worse have been recorded (Warren[14]), and as a basis for comparison they show what infinitely better results have been obtained when the help of a surgeon has been sought. The largest series of cases of pyloric stenosis with which I am familiar is Still's series of 248 cases[9]; his recovery-rate in private cases treated medically is a wonderful one, yet his view is that "when the mother is breast-feeding the infant, it is usually the wisest course to proceed at once to operation." He comes to this conclusion after discussing, as I have done, the effect on the mother of the anxiety engendered by lengthy medical treatment. In the following tables I have given for comparison with my own results those of Still (Table II.), and the results of Rammstedt's operation as given by Gray and Reynolds, and also by Poynton, Higgins and Brydson. (Table III.) The figures of the last group of writers are the most recently published ones, and show quite the best results so far recorded by British workers.

TABLE II.—*Comparison of Results of Cases Treated by Medical Means and by Rammstedt's Operation.*

Gray and Reynolds	42	17	41*
Poynton, Higgins, and Brydson	57	42	73·6†

* Calculated from statistics given in paper.

† These authors give 70 per cent. recovery in 55 cases. They, however, exclude two cases (one cured) which should be included to compare with my series. Their percentage of cures is, however, calculated incorrectly, it works out at even a better figure than the one they give.

The operation has been done for me by several of my surgical colleagues, but in the majority of cases by Mr. Seymour Barling; it is interesting to note that the results obtained improve with each year, the recovery-rate for 1923 in 17 cases, being 70·5 per cent. If an analysis of the 32 fatal cases be made it is found that the length of time they survived the operation can be grouped thus: Not more than 24 hours, 9 cases; 1–3 days, 5 cases; 3–7 days, 4 cases; 7–14 days, 6 cases; over 14 days, 8 cases. In 12 cases the cause of death was post-operative collapse; in seven cases diarrhœa and in five cases bronchopneumonia. In two cases the bronchopneumonia was probably a complication of whooping cough. Hæmorrhage, peritonitis, and cerebral thrombosis were responsible for one death each, and in one other case, as I have already pointed out, the operation was an incomplete one.

I feel convinced that early diagnosis and early operation are essential to give the child the best chance of recovery. The reason why my results after Rammstedt's operation are so much better in private than in hospital cases is, I believe, because the former group of cases are usually diagnosed and operated upon earlier than the latter group. The truth of the statement that the shorter the time of duration of symptoms before operation the greater are the chances of recovery has been conclusively demonstrated by Poynton, Higgins and Brydson.

Conclusion.

In these lectures I have tried to lay before you the various views held as to the causation of infantile atrophy, the reasons for and against such views, and fresh experimental data in support of what seems to me to be, in the present state of our knowledge, the best explanation of these wasting disorders of early infancy. I have attempted to prove three theses:—

1. That in many cases there is a great deal of evidence in support of the view of the earlier English writers—Charles West, Eustace Smith, even Pemell and "J. S."—that the onset of infantile atrophy is due primarily to the supply of insufficient and unsuitable food.

2. That however the initial loss of weight has been produced the continuance of the atrophic state depends upon an altered metabolism and not upon disorders of digestion and absorption.

3. That the rational treatment of pyloric stenosis of infants includes the performance of the Rammstedt operation at the earliest possible moment.

If the arguments put forward have failed to carry conviction the reason is, I believe, not because the foundations on which they are based are unsound, but because I have not builded well.

Lastly, I would like to express my most grateful thanks to my colleagues, medical, nursing, and laboratory, for the generous help they have afforded me without which these lectures could not have been given; indeed, any merit which the lectures may possess is largely due to their assistance.

THE LATE DR. W. H. BARRETT OF SOUTHPORT.—Dr. Barrett died at Le Havre on April 22nd on board his yacht *Muriel*. Owing to the breaking of a gangway ladder about a month ago he met with grave injuries, and whilst recovering therefrom on board he was attacked by a fatal pneumonia. The remains were taken to Southport and laid to rest there on April 24th. Dr. Barrett had retired from an extensive practice in Southport about ten years ago. Ever a keen sportsman, he took great interest in motoring and was an active yachtsman and a member of the Royal Clyde Yachting Club. After graduating M.B. and C.M. at Edinburgh University in 1883, he was for a time pathologist to the Royal Edinburgh Asylum, and lecturer in Queen's College, Belfast. He then moved to Southport, where he soon acquired a large practice and was an hon. medical officer of the local infirmary. His winning personality will be greatly missed by many friends in and beyond Southport. Dr. Barrett leaves a widow, two sons, and a daughter.

THE RELATIONSHIP BETWEEN THE ISLETS OF LANGERHANS AND THE ZYMOGENOUS TISSUE OF THE PANCREAS.

BY SWALE VINCENT, LL.D., D.Sc., M.D.,
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF LONDON
(MIDDLESEX HOSPITAL MEDICAL SCHOOL).

IT is generally assumed that the pancreas consists of two separate and distinct parts, the zymogenous tubules and the islets of Langerhans. It is further accepted by many that the "internal secretion" of the organ is carried out by the islets and not by the zymogenous tissue. Thus, it follows, according to the current view, that "insulin" is formed only by the islets. The fundamental question at issue concerns the claim of the islets to rank as organs or masses of tissue *sui generis*. The experimental evidence has been conflicting as to whether these bodies maintain a constant form and mass under varying physiological conditions of the pancreas, or whether, on the other hand, they may undergo changes concomitantly with changes in the pancreatic parenchyma as a whole.

History.

My own interest in the subject was aroused 20 years ago by the appearance of a very important paper by Dale,[2] who found that an increase in the amount of islet tissue may be induced by exhausting the pancreas by means of secretin. Vincent and Thompson [9] [10] [11] came to the conclusion that the islets are part and parcel of the general secreting tissue of the pancreas. Under certain conditions (inanition) the islet tissue is markedly increased, most probably at the expense of the zymogenous tissue. If, after a period of inanition, an animal be restored to its normal condition, the pancreas likewise returns to the normal, the amount of islet tissue becomes normal, and the presumption is that alveoli are reconstructed from islets. The islet columns are frequently in complete anatomical continuity with the surrounding zymogenous tubules, and all kinds of transition forms are common throughout vertebrates. The work of Dale was also confirmed.

Bensley in 1911[1] employed methods different from those of Vincent and Thompson, and came to very different conclusions. It is largely owing to the acceptance of Bensley's results that the majority of authors believe in the "separate organ" theory of the islets.

A communication by Lane[6] had appeared in the year 1907. In this attention was called to two different kinds of cells within the islet; specific granules were described in each kind of cell.

Since the date of Bensley's communication several papers have appeared on the subject. Among those who supported the view that the islets are independent structures may be mentioned Weichselbaum,[12] [13] Homans,[3] and perhaps the majority of pathologists. On the other hand, Laguesse [4] [illegible] and Saguchi,[8] not to mention others, have strongly supported the views put forward by Vincent and Thompson.

Structure of the Islets.

Some years ago I carried out (in conjunction with J. P. Parsons) an investigation, using the histological methods of Lane and Bensley, and saw no reasons for changing my view. Continuity between islet and zymogenous tubules is a common occurrence throughout vertebrates. But Bensley, and others who agree with him, insist that the islet cells constitute a double histological entity, and that each of the two kinds of islet cell is distinguished from the zymogenous cells by absolutely characteristic cytological features—that is to say, by the possession of specific granules reacting to particular stains. In other words, although the zymogenous tubules may appear to run into the islet tissue, there is in reality a sudden change when we pass from a zymogenous cell to an islet cell, since the latter contains none of the specific contents of the former, and possesses for its part specific granules peculiar to itself. On this view no cell may rank as an islet cell unless it contains granules of one or other variety.

It may not be known to those who have not worked at the question how far the attitude just presented depends upon the results of work by two particular histological methods—staining by neutral gentian and acid fuchsin and methyl green. In the case of these stains it is impossible to be quite sure that we have used quite the same staining fluid as that used by previous workers. The quantitative details for making up the staining fluids are not very explicitly given, and there is considerable confusion as to the precise chemical nature of the dyes themselves.

The specific nature of the A and B granules has not been proved. Using the Lane B staining method with material from the guinea-pig we found that the histological picture corresponds fairly well with what Lane, Bensley, and others have described; some of the cells ("B cells") appear violet, due to the presence of violet-stained granules, and others (the "A cells") faintly coloured with the orange G. Employing Lane's method for the A cells, it was not always easy to mark their limits, and their nuclei did not appear to differ in shape from those of the B cells. Speaking generally, the A and B cells do not come out as clearly as one would expect after reading the descriptions of the above-mentioned authors. Sometimes it is even difficult to say whether a particular deeply-stained cell is to be put in the A or B category; the tint is sometimes brownish mixed with violet, or vice versa. In many cases only part of the cell is stained, in other cases one part of the cell stains more deeply than another. Thus the A cells (Lane's method) may be deep violet in one part, and the colour may fade away so that the other end of the cell resembles in tint the almost unstained surrounding B cells. It is thus by no means clear that we have to deal with two different types of cell. It seems possible that there are various stages of activity revealed by differences in staining reaction. Moreover, the investigation convinced us that the acinous cells of the pancreas contain granules which give staining reactions very similar to those of the B cells of the islets, and if the acid fuchsin and methyl-green method be employed, we find scattered throughout the pancreas certain cells which stain deep red, while others are green.

It cannot be allowed that the criterion for "transition" above referred to should be insisted upon. We can conceive that a real transition between zymogenous and islet cell might present itself in a different way. The number of zymogenous granules in an acinous cell might become gradually reduced as one approaches the edge of an islet, until at a certain point the cells are found to contain no such granules. Careful examination of these might then reveal the granules which are supposed to be specific for islet cells. Thus, there might be a certain degree of suddenness in the occurrence of the "islet granules," though the total change might reasonably be regarded as a real transition from one tissue to the other. This seems the more plausible in view of the anatomical continuity which is admitted to occur.

Effect of Inanition on the Amount of Islet Tissue.

Vincent and Thompson studied the effects of inanition in the dog, cat, pigeon, and frog, and reported that in these animals the effect is markedly to increase the amount of islet tissue at the expense of the zymogenous. These results, so far as concerns the bird, have been fully confirmed by Laguesse. Since that time the effects of inanition have been studied upon the rat, gopher, guinea-pig, and hen, with results entirely confirmatory of those of Vincent and Thompson. Bensley is of opinion that the apparent increase in islet tissue is accounted for by the normal variation which occurs. If this were the case it might surely happen in many cases that the mistake might be in the opposite direction. So far as we can learn, Bensley does not appear to have reckoned with the *amount* of islet tissue under any conditions. By his method he has counted the *number* of islets, and says that this is constant. Now surely the important point is the actual amount of islet tissue. Three or four large islets might easily represent a vast increase in islet tissue over a score of small ones. What happens, indeed, in many cases is that the very small islets, consisting of only a few cells, are increased enormously during inanition. Bensley's method is incapable of noting such a change. In the work carried out in conjunction with F. D. Thompson the ratio between the amount of islet tissue in the inanition animal and that in the normal pancreas was calculated by drawing the islets in ten successive sections with a camera lucida, and cutting out and weighing the paper enclosed in the outlines. In the pigeon the ratio was as 4·22 to 0·93. In the later investigations the planimeter was employed. By this method the amount of islet tissue in the hen after a period of inanition was found to be three times as great as in the normal.

The islet tissue found after inanition (including presumably many new patches) always stains well by the Lane B method. Thus they cannot be confused with patches of simply exhausted zymogenous tissue.

Effects of other Changes of Conditions on the Amount of Islet Tissue.

In rats a pure carbohydrate diet markedly increases the amount of islet tissue, and in frogs extirpation of the spleen produces a similar effect.

Conclusions.

From the above considerations we may with considerable reason conclude that the islets of Langerhans are not separate and distinct organs. They represent temporarily modified portions of the secretory tubules of the pancreas. It is true that by certain modes of staining some cells of the islets may be differentiated from others, but the differentiation may point to different stages of activity and not indicate two distinct types of cell. Moreover, these are signs of a similar differentiation among the cells of the zymogenous tissue. The islets are anatomically continuous with the zymogenous tubes, and the two kinds of tissue may be seen to merge one into the other. During inanition and under other circumstances the amount of islet tissue is regularly and markedly increased.

The view here presented is strongly supported by Oertel[7] from the pathological standpoint. This author has with great justice pointed out how meagre is the evidence which would convict the islets of Langerhans of being responsible for the secretion of insulin.

At the time that the discovery of insulin was reported by the Toronto investigators, I felt considerable doubt as to whether the controls were sufficiently rigid, and as to whether insulin might not be obtained from glandular organs other than the pancreas. At my suggestion E. C. Dodds and F. Dickens* have applied their method to the submaxillary gland of the ox, and have found that this organ yields 710 original Toronto rabbit units per kilo of gland. Several observers of the Toronto School have prepared insulin from various organs and tissues of the body, but the fact that such large quantities as we have just quoted can be prepared from a gland so like the pancreas in general structure cannot be without some fundamental significance.

It is yet too early to state dogmatically the relation between the fact discovered by Minkowski that extirpation of the pancreas produces diabetes, and the other fact that a pharmacologically active substance capable of reducing the blood-sugar can be obtained from the pancreas and other organs.

THREE CASES OF
NEW GROWTH OF THE APPENDIX CÆCI.

BY HILDA K. WHITTINGHAM, M.B., B.S. LOND., D.P.H.,
PATHOLOGIST TO THE SOUTH LONDON HOSPITAL FOR WOMEN.

Two distinctly different kinds of new growth in the appendix cæci have been described under the name of carcinoma. One, a columnar-celled growth, has the histological characteristics of the type of carcinoma which occurs commonly in other parts of the intestinal tract, and exhibits, by a general dissemination of the new growth, the usual features of malignant disease. The other kind of growth is spheroidal-celled, and, although showing microscopic appearances suggestive of a carcinomatous nature, does not present other usual signs of malignant disease; invasion of the tissues is localised, and there is no tendency to metastatic dissemination. In its histological characteristics, and in the localised limitation of its invasion of the tissues, the second kind of new growth of the appendix resembles closely the type which has been described by Krompecker under the name of basal-celled carcinoma.

The three following cases, all of which belong to the second group, have occurred amongst the cases in which the appendix has been removed at the South London Hospital for Women during the last three years.

CASE 1.—A single woman, aged 21, admitted under the care of Miss E. Davies-Colley, with a diagnosis of chronic appendicitis. There was a history of an acute attack some two years previously, with persisting pain and tenderness about the right iliac region.

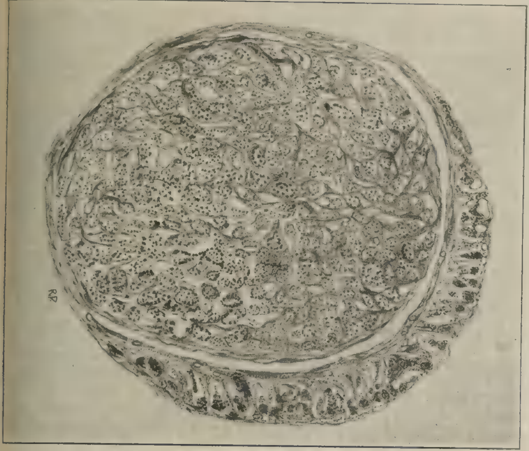
CASE 2.—A married woman, aged 39, suffering with a fibroid tumour of the uterus with severe menorrhagia, admitted into hospital under the care of Miss M. Houndsfield. In the course of an operation for the removal of the fibroid tumour it was found that the appendix was adherent to neighbouring parts, and that its tip was enlarged and bulbous. In this case there was not any history of past illness or symptoms suggesting any disease of the appendix.

CASE 3.—A married woman, aged 31, suffering from menorrhagia, was admitted under the care of Miss Davies-Colley. There was some tenderness in right iliac region, and an exploratory operation carried out. It was found that the appendix was adherent to the neighbouring parts, and presented a sharp kink at about the middle of its length.

Remarks.

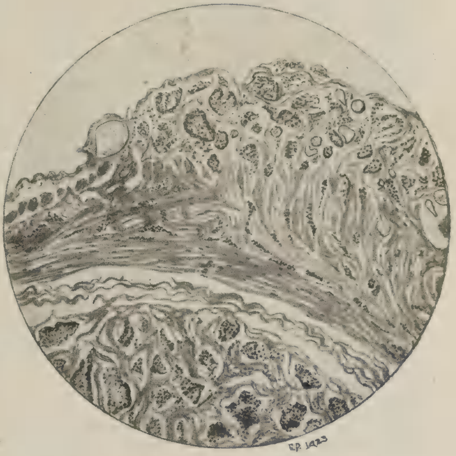
All three appendices showed definite macroscopic changes which were suggestive either of new growth or of tuberculosis. In Case 1 the new growth was presented as a general, indurated, thickening of the proximal portion of the appendix, the area of thickening was of whitish appearance, and the lesion was not circumscribed so definitely as in the two other cases. In Cases 2 and 3 there was an oval nodule of caseous appearance in the wall of the appendix. In Case 2 the nodule of new growth occupied the tip of the appendix, and the lumen of the tube above was pervious throughout. In Case 3 the new growth was situated at about the middle of the length of the appendix, just where the kink had occurred, and appeared to occlude the lumen completely.

FIG. 1.



Drawing of transverse section through new growth and appendix wall from Case 3. (Both figures are from drawings by Dr. Ruth Dingley.)

FIG. 2.



Showing portion of wall of appendix from Case 3.

In all three cases the histological appearances of the new growth were essentially similar (see Figs. 1 and 2). In each case the new growth consisted of columns, or continuous tracts, of spheroidal cells, showing a differentiated peripheral zone in which the cells tended to assume a cubical form. These columns of cells were included in alveoli formed by a fibrous reticulum, or stroma, the amount of which, relatively to the mass of spheroidal-cell growth, varied considerably in the three cases. In Cases 2 and 3 the new growth was represented mainly by the spheroidal cells, and the bulk of the fibrous reticulum was relatively small; the appearances were those of an encephaloid carcinoma. In Case 2 the bulk of the fibrous reticulum was more considerable and the general appearance was that of a carcinoma of the scirrhous type. In Case 3 the new growth had apparently occluded the lumen of the appendix completely. The lining epithelium had disappeared and only traces of the submucosa—in the form of small, isolated, masses of lymphoid tissue—remained. In this case the new growth had extended, through the muscle coat, to the subperitoneal layer. In Case 1 all trace of the mucosa had disappeared. In Case 2 the new growth appeared to be confined strictly to the muscle coat, and the mucosa was intact throughout.

In none of the three cases were the appearances those of a carcinoma originating in the epithelium of the intestinal mucosa, and alternative explanations of the cause of the new growth have to be considered. Some pathologists have suggested that these new growths of the appendix originate from an embryonic "rest." Other pathologists have regarded these new growths of the appendix as being of the nature of endotheliomata and, at any rate, as originating from some inflammatory condition of the appendix. In connexion with the latter hypothesis it will be noticed that in all of these three cases there was anatomical evidence of past inflammation of the appendix. In addition, there was in one case a quite definite history of an attack of acute appendicitis some two years before the new growth was discovered; and, in a second case, the new growth was discovered in the course of an operation for the relief of what appeared to be a chronic appendicitis. It should be added that, up to the time of writing and one year after the removal of the appendix in the third case, the several patients have remained free from any indication of recurrence of any trouble connected with the new growth which was removed by operation.

Note.—Since writing the above, a fourth case of new growth of the appendix has been operated on at the hospital. The patient was a married woman, aged 35 years, who was admitted under Miss Davies-Colley for uterine fibroids. At the operation the appendix was found to be tightly bound down; there was a marked constriction near the tip. A small yellowish nodule was found at the tip: the microscopic appearances of this nodule were similar to those in the other cases described.

THE PSYCHOLOGY OF VERTIGO.

By W. F. MENZIES, M.D. EDIN., F.R.C.P. LOND.,
MEDICAL SUPERINTENDENT, STAFFORDSHIRE MENTAL HOSPITAL, CHEDDLETON.

IN the endeavour to explain some common intracranial phenomena, whose physiological bases are little open to direct observation, it is usual to formulate theories; these are certain to be wrong, but if they are in accordance with observed facts they form for the time being useful working hypotheses. Vertigo is one of the phenomena which are not easy of approach from a common angle, coming as it does into the province of the general physician, the oculist, aurist, neurologist, and psychologist. In the recent combined discussion at the Royal Society of Medicine many facts from these various viewpoints were recorded, but the very nature of such a discussion precluded the possibility of correlating them.

Sequence of Processes Concerned.

It is essential, for the purposes of analysis, to dissociate the physiological processes concerned in a vital phenomenon from its realisation in consciousness. Of course, both are biochemical, but the latter is secondary, and is of the nature of awareness arising from emotility. Thus, the emotion of shame, the sensation of heat in the face and visible blushing are intimately associated, yet any one or any two or all three may occur in a given case. Again, vertigo, ataxia, nystagmus, headache, and a feeling of fullness in the head are nearly connected with changes of posture, yet any or all of them may occur in any combination. The hypothesis is here formulated that vertigo is a purely subjective sensation, and is the realisation in consciousness of the instinctive emotion of anxiety connected with the maintenance and adjustment of antigravity postures. Some clinical examples of the emotional nature of the condition are given below, but there are two other suggestive facts—viz., that the reaction time of vertigo is two to three seconds—i.e., that of an emotion, as opposed to the ·12 seconds of a cerebral reflex, and that hitherto no direct fibre connexion has been traced between the vestibular nuclei and the thalamus. Such terms as "objective vertigo" are misnomers, tending only to confuse definitions. Under this hypothesis the processes which result in vertigo are five in number: (1) a peripheral afferent stimulus, ocular, aural, or somatic; (2) a vestibular stimulus; (3) an adjustment response from intracranial and splanchnic plain muscle and from skeletal striped muscle; (4) an emotion; (5) its realisation in consciousness.

The reflex systems controlling antigravity postures which are centred chiefly in the various vestibular and other nuclei in the floor of the fourth ventricle, whose anatomical correlations are supplied by the median longitudinal fasciculus and vestibulospinal tract, and whose "locknut" is the cerebellum, receive their afferents from the semicircular canals, from the optic path in both its collicular and geniculate elements, and from skin, joints, and muscles. These systems have become increasingly intricate as the erect posture was gradually assumed, and now necessitate never ceasing changes in intracranial and vascular tonus in order to maintain a constant supply of oxygen to the neurons.

The Cortical Component.

For the purposes of quick adjustment of blood-supply the cranium may be regarded as a closed box, wherein fluid pressure is constant. The sympathetic fibres in the vessel walls are scanty, but their action is vital. Every change in posture is instantly compensated from the cardiac and splanchnic areas. Since the quantity of C.S.F. is minimal then, if more arterial blood be required the venous sinuses must partly empty; we assist this process when we instinctively inspire on rising up. But there is one exception to the closed box metaphor—viz., the vestibule and canal system—and it is precisely because the endolymph is not minimal and is free to transmit waves, that it so delicately registers the blood changes which it shares with all other parts of the encephalon and membranes. In this connexion it should be remembered that the vascular and sympathetic supply to this system is double, for internal vestibular branches arise from both carotids and vertebrals. Intracranial pressure may vary widely within certain physiological limits, and normal adjustments do not excite consciousness, but when maladjustment occurs, whether from excessive and confused stimulation, or from hampered and irregular plain muscle response, an emotional outflow is liable to be excited and the resultant conflict may enter consciousness. It may be asked why we should invoke the cortical component at all, why not be content with the pressure adjustments in the canals. The reason is that, on the one hand, intracranial adjustments are, like so many other sympathetic processes, massed reflexes, affecting equally vestibule, medulla, and cortex; and, on the other hand, there is sufficient evidence from the mental confusion, past-pointing, sensation of movement in the plane of stimulation, and other considerations of the accompanying mental state that this cortical component of vertigo exists and that it is primary—i.e., not received secondarily by way of the thalamus. What comes by the thalamus is the secondary emotion, later in the cycle of events. Likewise the medulla shares in the reflex, and vertigo from inhaling the morning cigarette is probably due to carboxylhæmoglobin in its vessels.

The Fear of Unconsciousness.

The maintenance of an adequate blood-supply to the brain is a primitive reaction, for the unconscious animal is helpless before its enemies and may very soon be a dead animal. So the fear of falling has from the earliest human stages been associated with the fear of unconsciousness. In this particular instance the warning from the canals and the quick alarm and vigorous response in plain and striped muscle awaken a defensive emotion, with adrenalin outflow and the rest, which is registered in the thalamus and thereafter conveyed to the cortex in strict accordance with the Lange-James theory. Normally, the physiological limits of the stimulus awake no emotion, then, of course, no vertigo follows. Although we know little of the endocrine and biochemical relations of an emotion, and practically nothing of its realisation in consciousness, beyond the association of pleasure with a free, and unpleasure with a restricted activity of the cortical oxidases, yet some such conception as that outlined here would appear to be necessary in order to explain the various clinical appearances of vertigo in both functional and organic conditions; mere intracranial tonus or atonia alone will not produce it. It is well known that section of the cervical sympathetic causes permanent ipsilateral dilatation of the arterioles in striate body, thalamus, and cortex. In a case of puncture of internal carotid from wound of neck, involving ligature of the common trunk, cervical sympathetic paralysis was present, but no vertigo. Again, it is recognised that at the onset of the epileptic fit the cerebral arteries are in spasm, yet vertigo is complained of by only a small percentage of those who describe a visual or auditory aura.

I cannot pretend to any opinions concerning intra-aural states beyond the routine neurological examination, but we are now in a position to consider some of the manifestations of vertigo in general medicine. The symptom is present in early paralytic dementia, where the cortex is still comparatively intact and anxiety or depression prevails. Later on, in the exalted or demented stages it is absent, although ataxia may be obvious. And so also in disseminated sclerosis the later stages of mental hebetude abolish it, although the patient can scarcely walk. A transient mimicry of this difference is to be observed in early alcoholic intoxication. Many cases of miners' nystagmus are unaware of the oscillations, and in these vertigo is unknown until some fellow workman, or the miner's agent, or too frequently the medical man, informs the patient of his condition. Thereafter all sorts of subjective sensations may arise, headache, diplopia, wavy pavements, nyctalopia, and so on, until ultimately hysteria or the anxiety complex or melancholia becomes established.

Vertigo is rare in the dark, and the neurasthenic who can scarcely walk down the street in the day-time will hurry on half-sideways at night, looking over his shoulder constantly to see who is following him. The absence of the usual visual stimuli does not come in here, for, of course, we do not walk at all if darkness is absolute. Giddiness is common to one standing on a height, but not when looking up into the sky from the ground level, although near objects are absent from the field in either case. Massed reflexes are wonderfully true to type, and their long phylogenic history brings them all for practical purposes into the class of conditioned reflexes. But if a new situation arises and if unaccustomed conditions are presented the whole process is apt to go wrong and, particularly, the vascular adjustments are confused or inadequate or excessive, and in any such case an emotion is excited in order that awareness to the danger of falling may be aroused in the organism. Syringing the ear and the vestibular reaction are instances of this. In sea-sickness the vestibular afferents are out of harmony with the optical. Birds are, from the nature of flight, peculiarly susceptible to vestibular variation, and from the time they leave the nest balance without fear on a swaying bough. But a few swings round by the feet produce the hypnotic state, complete paralysis, or even coma in a fowl, because the vestibular stimuli are now entirely foreign to instinctive experience.

Evidence from Morbid Anatomy.

In the toxic psychoses, notably in delirium, the post-mortem findings in the neurones—cloudy swelling, chromatolysis, vacuolation, and the like—show us how profoundly blood states influence the cortical oxidases, in the slighter degrees of these mental troubles—e.g., melancholia—headache, confusion, and vertigo often coexist. Nor can we doubt that the blood state will affect the canals equally; and so the toxic element can never be left out of account in the vertigo of anaphylactic or gastric conditions, anæmia, or high blood pressure. The mechanical factor in the last two must produce confusion of afferent stimuli out of accord with those produced by the toxic element, and in anæmia oxyhæmoglobin is, for a given volume of blood, deficient. Arterio-sclerosis is often associated with high tension, and the irregular plain muscle response due to impaired vessel walls not only leads to uneven cortical blood-supply, but also arouses a defensive emotion directly. A similar effect is produced by subtentorial new growths, especially at the cerebello-pontine angle, which not only increase intracranial pressure by obstructing the outflow of venous blood, but also bring about local anæmia. Valvular heart disease limits arterial flow and retards venous return, hence deficient oxidation.

Among the cases largely mechanical in causation the classical example is head injury, especially with fracture. Here the growth of scar tissue and thickening of membranes may upset the whole sympathetic mechanism for regulating intracranial tension and hopelessly bind down the vessels. It is well known that postural headache and vertigo persist indefinitely beyond the early concussion period, as in a case of gunshot wound from shrapnel in the Boer war 25 years ago. The man earned full wages as a bricklayer and mounted ladders freely; he had learned to disregard the vertigo which was still constantly present, for experience had taught him that he would never actually fall.

The above conception would appear to cover most of the conditions in which vertigo may appear, but whatever the associations, it arises only as an emotional outflow of instinctive fear. In the falling dream anxiety appears as a vestibular hallucination; the blood pressure rises as we awake, but the anxiety is adequately symbolised and vertigo is absent. If the symbolisation is imperfect, as in the fighting dream, foes may appear to dance round the patient on all sides, or he may imagine himself turning about rapidly and striking in all directions. On awaking such patients constantly complain that the room is turning round, and if they jump out of bed may fall to the ground.

Clinical and Laboratory Notes.

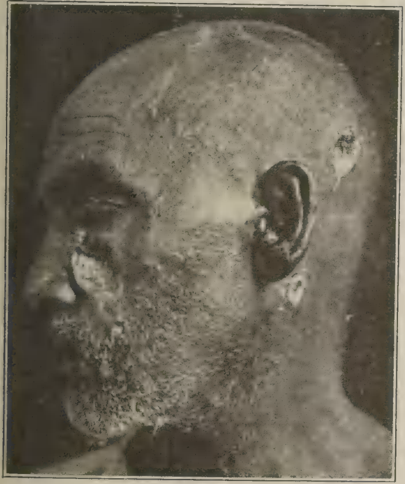
RHINOSPORIDIUM KINEALYI.

BY W. LEONARD FORSYTH, M.B., CH.B. GLASG.,
MAJOR, I.M.S.

(*From the Department of Pathology, Madras Medical College.*)

THE following case is of interest on account of its rarity.

FIG. 1.

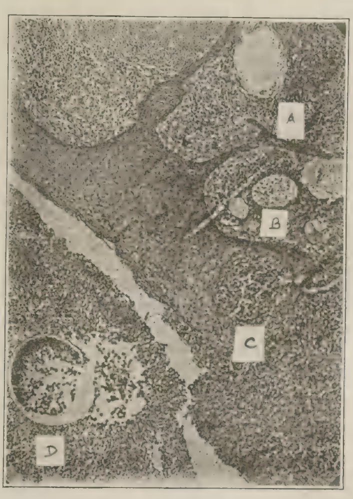


Showing suppurating growths of *Rhinosporidium kinealyi.*

M. H., aged 55, a resident of Calicut, on the West Coast of India, was admitted to the wards of the General Hospital, Madras, under the care of Major K. G. Pandalai on August 8th, 1923. Fifteen years ago patient had a small tumour in left nares which bled easily and freely—a feature of this disease. The growth persisted until three months before admission, when it spontaneously disappeared, and his nose is now free from obstruction. On the same side of the face, however, suppurating growths have appeared in the regions shown in Fig. 1. His left lacrymal sac is swollen, and probably harbours there also rhinosporidial infection. He had also a swelling under the palpebral conjunctiva of the left lower eyelid which has now healed.

Operation.—Excision of the papillomatous masses under local anæsthesia was performed by the surgeon and submitted for pathological report. The nature of the condition was not at operation suspected and the illustration shows only their site. Sections from all the areas (Fig. 2) show the parasite of rhinosporidium.

FIG. 2.



From microphotograph of a section. A, B, C, D are placed below foci of rhinosporidium.

In 1917 T. S. Tirumuti described in the *Practitioner* a series of cases, and Castellani in his Manual of Tropical Medicine mentions cutaneous surfaces, but does not quote any particular case, and so far as we are aware no case of rhinosporidium in a subcutaneous position has been previously reported in the Madras Presidency. The mode of infection by this sporidium still remains obscure, but it would appear possible that this individual auto-inoculated himself from his original nasal infection. No insect vector would appear to be necessary, and even in an original infection direct contact is suggested as a mode of spread.

THE SOURCE OF INFECTION WITH *HETEROPHYES HETEROPHYES* IN EGYPT.

BY M. KHALIL, M.D., PH.D., M.R.C.S. ENG.,
ASSISTANT DIRECTOR OF INVESTIGATION IN ANKYLOSTOMIASIS AND BILHARZIASIS IN EGYPT.

Heterophyes heterophyes (Siebold, 1852) is a trematode parasite in the intestinal tract of man, dog, and cat in Egypt. So far the life-history of this parasite and the source of infection are not known. It was, however, suspected that the second intermediate host would be found to be a fish, being a common food of the three definitive hosts. Examining the Egyptian mullet (*Mugil cephalus*), a trematode cyst was found amidst the muscle fibres of this fish in three out of eight fishes examined, the encysted cercaria being about 0·2 mm. in length. A study of the anatomy of the cercaria revealed the presence of a genital sucker lying close to the ventral sucker, a peculiarity of some members of the family *Heterophyidæ*.

A number of young kittens which harboured no heterophyes, as revealed by repeated examination of the fæces, were fed on the infested fish. After four hours cercariæ freed from their cysts were recovered from the small intestines. After 24 hours the parasites showed differentiation in the genital organs. In seven days many of the parasites, although smaller than normal, contained ova. Adult heterophyes of normal size were recovered on the fourteenth day.

These findings are interesting in being the first recorded example of a salt-water fish acting as a carrier of a parasite of man. So far search for intermediary hosts of human parasites has been confined to fresh-water fauna. The Egyptian mullet is found occasionally in the Nile, near its estuary, and the particular examples found infected were caught in the salt-water lake of Manzalah, near Port Said.

Heterophyes heterophyes infection causes dysenteric symptoms in man with occasional passage of blood and mucus. Experimental animals reveal inflammation of the mucous membrane of the small intestine.

The ovum of this parasite is one of the smallest found in human fæces, hence its presence is overlooked in a casual examination, and this may account for the small number of recorded cases of infection with heterophyes.

THE LATE DR. E. JACKSON.—By the passing of Edwin Jackson, M.R.C.S. Eng., J.P., at a ripe age at his home in Whalley Range, Manchester, on April 28th, his many patients have lost a wise and kindly counsellor, and the city one of its most diligent social workers. At the city police court, the stipendiary magistrate expressed his sincere regret and that of his colleagues, and tendered their deep sympathy with Dr. Jackson's relatives in their bereavement. A graduate of the University of London (1872) and Victoria University (1882), Dr. Jackson took the M.R.C.S. in 1876, after passing his medical studies in what was then the Royal School of Medicine in Manchester. He was for a time surgeon to the Manchester Day Nursery and Cottage Hospital, and a physician assistant at the Royal Infirmary. Dr. Jackson was deeply interested in the social, charitable, and religious work of the neighbourhood in which he practised, besides being a most industrious and efficient magistrate, and by his death the poor of his district have lost a valued and ever-ready friend.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF GYNÆCOLOGY AND OBSTETRICS.

A MEETING of this section was held on May 1st, Mr. T. G. STEVENS being in the chair.

Prof. LOUISE MCILROY read a preliminary communication, from herself and jointly with Miss D. L. LEVERKUS, entitled

Changes in the Polarity of the Fœtus during the Later Weeks of Pregnancy.

The authors said that the progress of antenatal work threw fresh light on abnormal fœtal presentations, and led to a questioning of the theories set forth in the books. The object of the present research was to ascertain the frequency of polar rotation of the fœtus in the uterus, and its influence on prognosis and treatment in obstetrical cases. There was a tendency for the fœtus to right itself to a cephalic presentation. The chief point concerned the changes from the cephalic and pelvic polar presentations, and the conclusion of the authors was that the chief factor influencing the persistence of pelvic polar presentations was extended legs; the lower limbs acted as a brace to prevent the natural curve of the spine taking place. If the spine of the fœtus was curved and the limbs were flexed, free rotation easily took place. In 22 pelvic polar deliveries it was found that extension of the legs had occurred in eight cases. The authors considered that the localisation of the fœtal heart sounds round the umbilicus was not a very reliable guide in diagnosis. Spontaneous version occurred so frequently that it was well to leave the fœtus to adjust itself in the earlier weeks, and as version usually took place between the twenty-eighth and the thirty-fourth week, no attempt at interference should be made before that time. If the pelvic presentation persisted in a primipara after the thirty-sixth week, version was advisable, as it might prevent complications at labour.

Dr. R. A. GIBBONS said that in many instances he had performed version externally after the fourth week before delivery. The important point which had been brought out was that these cases should not be interfered with until at least four weeks before full term.

Mr. EARDLEY HOLLAND agreed that extended legs caused much difficulty in the performance of artificial version, but said that the chief difficulty he had in external version was from the lower pole of the fœtus getting deeply into the pelvis. He always did external version whenever he found a breech, no matter what the pregnancy, with the reservation that if the external version was not very easy he did not persist; it was not worth while to do so until the thirty-sixth week. He had not known external version do harm; but in two cases in which external version had been performed successfully there was a small retro-placental hæmatoma.

Mr. A. W. BOURNE supported the authors' warning against too resolute attempts being made to turn the fœtus, because the placenta might thereby become separated. Also there was some danger of injury to the broad ligament. In doing external version the chief risk was of the engagement of the sharp wedge of the buttocks in cases of extended legs. At hospital the usual practice was to turn at about the thirty-sixth week. In about two-thirds of the cases in which attempts at version failed, spontaneous version occurred during the next two or three days.

Prof. MCILROY, in reply, said she had had no experience of harm or of hæmorrhage having occurred from forced version having been carried out, a practice she disapproved of. The shoulder of the fœtus might be rubbed against the edge of the placenta and an increasing hæmatoma result. Another important point was the risk of injury to pelvic veins. The external method of version alone was used by her.

Effect of Pregnancy on Renal Glycosuria.

Dr. **George Graham** described the case of a woman the subject of glycosuria who, after being under observation 13 years, became pregnant and was delivered of a healthy child. When taken into hospital she was passing 20 to 30 g. of sugar per diem, and the sugar concentration in the urine was 4 per cent. to 5 per cent. She was very drowsy, and her breath smelt strongly of acetone. After a stay of two months she was discharged as a case of diabetes mellitus, the outlook being grave. Two years later she was again taken into hospital, as, she having lived so long, her case was considered to be one of diabetes innocens. Under careful dieting her condition greatly improved. The baby was found not to be the subject of glycosuria. Dr. Graham said pregnant women were more liable to pass some sugar in the urine because the pressure in their kidneys was lower than in ordinary people. It was the presence of dextrose in the urine which rendered a case grave and demanded serious investigation.

Pregnancy Complicating Diabetes Treated with Insulin.

Dr. **Graham** also reported the case of a woman who had true diabetes and was treated with insulin throughout the period of gestation. The case was regarded as a grave one, because out of 66 such cases 27 were reported to have died either at the time of labour or within two weeks of delivery, while 23 per cent. died within the ensuing two years. The outlook of these patients had now been greatly improved by the use of insulin. Despite warnings and precautions, this woman became pregnant three weeks after the insulin was started. Two months later the sugar was 0·11 per cent., and later still it was increased to 0·19 per cent. At six months the question of terminating the pregnancy was discussed and negatived. The insulin dosage was increased, but the patient refused to take to her bed. The blood-sugar rose to 0·24 per cent., and the dose of insulin was increased to 15 units. The sugar then came down to 0·14 per cent., and the insulin dosage was reduced to 10 and 5 units after delivery, as the requirement of the body was then presumed to be less. The latest report was that the patient was definitely worse. Dr. Graham expressed his strong view that women with this disease should not become pregnant, as their resistance to infection was distinctly less than that of normal persons. He thought the reason women with diabetes mellitus who were pregnant died in coma was that they received a mild infection at the time of delivery. Insulin had been found to be excellent for any emergency operation.

Mr. **Bourne** spoke of a patient with true diabetes who, while under observation, had two children. During the first pregnancy she was treated with great care by dieting, &c., but had no insulin. At the thirty-sixth week labour was induced. She afterwards became very septic, but survived. Though strongly advised not to become pregnant again, she did so in six months. She was treated as before, again receiving no insulin. She did not lose weight. Cæsarean section was performed now in order to sterilise her, and she was fortified by being given a dose of insulin before the operation. Her puerperium was normal, and she expressed herself as feeling better than she had for some years.

Mr. **S. G. Luker** thought the outlook on these cases was unwarrantably grave.

Mr. **Holland** referred to a case which had true diabetic coma, and in the midst of the coma gave birth to a child at full term. Under treatment with insulin she did well, making an excellent recovery. On request, he sterilised her 18 months ago; she still had diabetes.

Presacral Tumours of Congenital Origin.

Mr. **Alexander Galletly** read a paper on a presacral tumour of congenital origin, with a case in which a cyst complicating pregnancy was removed by the abdomino-perineal route. The patient was a woman aged 43, who at the age of 13 had a swelling removed from the coccygeal region. At 32 years of age a similar swelling appeared in the same situation, and a second operation was carried out through the same incision. In 1920 she was delivered of a full-term living child, which was born without complications, though the perineum of the mother was badly torn. She had a second pregnancy in 1922, and then she noticed a swelling in the right buttock, which steadily increased in size. When eight months pregnant her doctor found that the fundus of the uterus had reached the infrasternal angle, and that the child's head was floating above the pelvic brim. By vaginal examination a cystic swelling could be felt. Cæsarean section was performed and a healthy living child delivered. At the operation it was seen that the retro-peritoneal cyst was firmly wedged in the pelvis. To obtain proper access to the cyst the uterus was removed, the cervix being left. The appendages on both sides were healthy. The cyst was tapped from above, and four pints of light brown fluid withdrawn. Three months later the patient was readmitted as the cyst had refilled. Mr. Victor Bonney operated under spinal and general anæsthesia, opening the abdomen by a sub-umbilical incision in the middle line. The bladder was raised, the rectum turned to the left side, the ureters isolated on each side, and the right internal iliac artery ligated in order to diminish the bleeding at the next stage of the operation. There were found to be several separate tumours each within a definite capsule. After removal of the cyst, a rubber drainage-tube was inserted and the gluteal incision closed. She now felt well and was doing her home duties.

Mr. **Victor Bonney** detailed the operation he performed in this case, remarking that endogenous teratomata were rarely present at birth, whereas the exogenous ones were always present at birth.

Mr. **A. C. Palmer** mentioned two presacral extra-peritoneal cysts which he had had to deal with in the last two years, not so large as in the case under discussion.

SECTION OF OTOLOGY.

A **meeting** of this section was held on May 3rd, Mr. **Sydney Scott**, the President, being in the chair.

Mr. **F. B. Gilhespy** read a paper on

Aural Surgery at a Fever Hospital.

He said that during the last few years otologists had been appointed to fever hospitals in increasing numbers and in some facilities for operations were provided. His own hospital had 500 beds, but a disadvantage was the fact that it was three miles from the centre of the city. He paid two visits each week, besides emergency calls. There were entirely separate divisions for diphtheria and scarlet fever. Most of the material was supplied by cases of suppurative otitis media in scarlet fever patients, though some cases of otorrhœa came from the diphtheria blocks. Each discharging ear case had treatment thrice daily, unless otherwise ordered. Reliance was placed on a thorough drying of the external auditory meatus and a cleansing of the external ear. When, last year, cases of impetigo developed in the ward, it was noted that the ears of the affected children showed great resistance to treatment, and since then each case had a separate gown and washing bowl provided. Ears might commence to discharge in the first week of scarlet fever, or this might not occur until the sixth or even the tenth week. If it occurred during the afebrile stage there seemed to be two modes of onset; one marked by an initial rise of temperature, often with pain, the other being painless and without any rise of temperature, so that the first indication was the finding of some discharge on the pillow in the morning. In the first type the rise of temperature might precede the discharge by a day or two, and if this danger-signal was appreciated, paracentesis could be performed in time. He emphasised the fact that the naso-pharynx was always primarily involved in scarlet fever, therefore at his hospital it was the custom to remove the adenoids if the ear discharge was not resolving. If the tonsils were found to be diseased they were removed at the same time. This could safely be done in the fourth week of an ordinary case of scarlet fever. In half of a series of 83 cases the adenoids alone were removed, and the results were equal to those in the cases from which the tonsils also were enucleated. The free bleeding following the adenoid operation relieved tubal congestion and hastened tympanic resolution in cases from which the amount of adenoid tissue removed was less than digital examination seemed to reveal. The average duration of the otorrhœa after the tonsils were removed was 15 days, a saving of a fortnight in comparison with cases treated in a special ear ward without operation. Each child received 2000 units of diphtheria antitoxin the day before the tonsil and adenoid operation, as a precaution against diphtheria, and, so far, no case had developed diphtheria after operation. Bleeding was stopped before the patient left the table, and no cases of delayed or secondary hæmorrhage had occurred. One child developed anterior poliomyelitis 16 days after the operation for tonsils and adenoids in the tenth week of the scarlet fever. Ionisation was of utility in helping to clear cavities remaining after mastoid operations, and in the conservative and radical operations which were needed. When cases entered the hospital with a history of chronic otorrhœa a few had been cured by the removal of adenoids. He had, previously to taking up this work, been impressed at a deaf and dumb institute by the number of children he saw deaf, presumably as a result of bad scarlet fever or measles in childhood. In three years at this fever hospital he had seen only one case in which the middle ear and the internal ear were attacked at the same time. That was a case of septic scarlet fever, in which facial paralysis developed within six hours of the onset of the discharge, and in a few days from the onset of the disease the child died. In these diseases the sinuses did not seem to be frequently at fault.

In conclusion, he pointed out the beneficial results from the early treatment of cases of scarlet fever otitis, for only when chronicity was established did the membrane tend to be widely destroyed. He thought arrangements ought to be made for dealing with cases of measles complicated by otorrhœa, for that disease occurred when the adenoids were at their most luxuriant growth, and timely treatment would probably prevent much wastage from ear disease in school and adult life.

Dr. Kerr Love agreed that there had recently emerged a more enlightened view in the profession as to the need for otologists in fever hospitals. Otologists in their ordinary work seldom saw cases of scarlet fever in the acute stage, while superintendents of fever hospitals seldom saw the end-results of suppurative otitis due to scarlet fever. No case of scarlet fever or measles suppuration in the ear should be allowed to leave the hospital until the discharge had ceased, even if it meant the performance of a mastoid operation, though this was only necessary when the condition existed before the patient came in.

Mr. T. B. Layton referred to the importance of following up scarlet fever and measles cases which suffered from otitis, in order to ascertain how much of the permanent ear trouble was due to those diseases, especially scarlet fever; also what was the possibility that the damaged ear—which clinically might be well on leaving the fever hospital—would be the site of a fresh micro-organismal invasion. It had been difficult to follow up the cases in London, because many of the children attended schools which were not under the London County Council. With regard to the performance of paracentesis, it was important to have an otologist easily accessible to do this at the moment the drumhead was ripe for it. In his experience, however, the operation was not always successful in stopping the discharge.

Mr. J. F. O'Malley said it would be important to know what was the incidence-rate of middle-ear suppuration in relation to the total number of scarlet fever admissions. Dr. F. F. Caiger (who was not an otologist) some years ago said that the incidence-rate was 15 per cent., and that it was greater from 3 to 10 years of age than at other ages. That led the speaker to think that adenoids was a large factor in the production of middle-ear infection, a view Mr. Gilhespy shared.

Sir James Dundas-Grant remarked that there was much to be said for the view that there were many cases in which the tonsils could advantageously be left while removing the adenoids. He had seen some cases of acute suppuration of the middle ear (not scarlatinal) in which the condition hung fire until the adenoids were removed, and improvement dated from that procedure. Out of 99 cases of scarlet fever in an epidemic among the patients without enlarged tonsils and adenoids the incidence-rate was 1 in 28, and among those with enlarged tonsils and adenoids it was 1 in 12. Removal of adenoids produced only slight shock compared with that from the tonsillar operation.

Mr. H. V. Forster asked whether in these cases of scarlet fever, measles, and diphtheria Mr. Gilhespy applied local treatment to the nose or throat—i.e., irrespective of whether or not they had ear trouble. He believed lavage and heavy spraying in a small child was a dangerous procedure, and that ear disease was liable to result. He always spared the tonsils if possible, as their removal was a grave operation in many of these children.

Dr. Albert A. Gray spoke of the work of Dr. W. T. Gardiner, of Edinburgh, who, in the presence of ear trouble, removed tonsils and adenoids at any stage of the disease, and with very good results.

The President pointed out that adenoids often seemed larger than they actually were because they were engorged with fluid. Usually he had removed adenoids at the time, and left the tonsils to be dealt with later. It was of no use dealing with the latter short of enucleation.

Mr. H. J. Banks-Davis said that if a child had an acute mastoid and at the operation on that adenoids were found, he removed them at the same time, always leaving the tonsils alone, especially as the raw surface left by removing them would provide a site for infection.

Dr. P. Watson-Williams asked the opener as to the use of an antiseptic spray in these cases, and advocated the spraying with collosol argentum, nearly pure, as a prophylactic measure. He agreed with the conservatism of sparing the tonsils wherever possible.

Mr. Musgrave Woodman asked as to measures for dealing with impetigo when it was met with. A case of the kind which occurred in his experience he cleaned out and scraped, but unsuccessfully. He agreed that if a mastoid operation was required, that was sufficient for the patient to stand; but often adenoids and tonsils were diseased together, and if the neck glands were enlarged removal of tonsils constituted an important factor in their subsidence.

Mr. Gilhespy, in reply, said he never removed tonsils or adenoids earlier than in the fourth week of the scarlet fever; mastoid disease had not developed before that stage. Discharge generally ceased as soon as the adenoids had been removed. He would not operate on a scarlet fever case in which the whole naso-pharynx was intensely congested. He could not give any indications for detecting when a tonsil was diseased. Once it had been diseased he thought its structure was so altered that it was never a normal body again, therefore at some time it should be removed. He believed the incidence of otitis in fever hospitals was correctly stated as 15 per cent., but he thought the figure was somewhat misleading, as the incidence of scarlet fever was greatest in the period 5 to 10 years, while that of measles was from birth to 5 years of age. No spraying of the nose was allowed by the medical superintendent; the nose was usually wiped out with antiseptics by means of cotton-wool.

Several otological cases were shown and discussed.

Reviews and Notices of Books.

PHARMACOPŒIAS OF THIRTY-ONE OF THE LONDON HOSPITALS.

Ninth edition. By PETER SQUIRE and PETER WYATT SQUIRE. London: J. and A. Churchill. 1924. Pp. 451. 12*s.* 6*d.*

SINCE the publication of the eighth edition of this well-known book of reference, the lamented death has occurred of Peter Wyatt Squire, and the present edition has been revised by W. S. Boyack, who assisted him in his editorial and compiling work for nearly 20 years. The book came into existence 60 years ago, when the first Peter Squire, being engaged in the preparation of the British Pharmacopœia, classified for his own convenience the formulæ used in the different London hospitals, to whose prescriptions he found reference was often necessary. He saw that such a classified collection of formulæ, some of the most valuable of which were not generally known, would be useful alike to medical men, pharmacologists, and pharmaceutists, and produced the first edition of this work with a success which has been steadily maintained. The last edition was published in 1910, and in our review of that issue the amount of revision that was then necessitated was indicated, for we noted that 26 of the London hospitals had produced new editions of their pharmacopœias within the preceding two years. The same need for careful revision is proved in this edition, for since 1910, 25 of the London hospitals have again re-issued their formulæ, making considerable alterations and adding many new recipes. We have now in this series a progressive history of pharmacy as conducted in 31 London hospitals, over a period of 60 years throughout which period the book has been a recognised work of reference to the medical profession.

In many of the hospital pharmacopœias whose contents have been abstracted the formulæ have been divided into sections representing the needs of the hospital generally, and the needs of the various departments; and where the departmental formulæ are given they are now specially indicated so as to distinguish them from the general hospital formulary. The prescriptions are arranged under the headings of the various preparations so that an immediate comparison may be made between the dosage and directions as they appear in the different institutions. There can be no question of the practical utility of a book which presents an exhaustive comparison of the pharmacopœias of the London hospitals, for in these institutions the formulæ will be selected for the best reasons which the knowledge of the day can furnish, while their selectors represent leading authorities on all therapeutic questions.

SOME GERMAN NEUROLOGY.

(1) DIE EXTRAPYRAMIDALEN ERKRANKUNGEN.

By Privatdozent Dr. A. JAKOB, Director of the Anatomical Laboratory of the Psychiatric Clinic in Hamburg. With 167 illustrations. Berlin: Julius Springer. 1923. Pp. 490. $7.20.

THIS is an excellent monograph. It contains a wonderful amount of personal material, including most varieties of the syndromes commonly considered "extrapyramidal," the value of which resides in the elaborate pathological examination appended to each case. As a result, we have in this book much less than usual of the unsatisfactory speculation as to site and degree of lesion which disfigures many purely clinical records. The chapters towards the close, on the pathophysiology of involuntary movement, will repay close study.

We consider that the immense attention given in the last decade to the corpus striatum has had one rather unfortunate sequela; the zeal of some investigators has outrun their discretion, notably in regard to schematisation of striatal syndromes. Dr. Jakob follows the Vogts too uncritically—though he provides an occasional welcome exception—as regards separate "striatal" and "pallidal" symptom-complexes, and as a consequence the reader will easily discover the mutually contradictory nature of not a few of the conclusions drawn. Dr. Jakob's own explanation of the pathogenesis of involuntary movement of the types of tremor and of choreo-athetosis is ingenious but incomplete, for it fails to take into adequate consideration the occurrence of these symptoms in cases where the lesions do not involve the mechanisms that he includes in his scheme. Further, he has not given any serious consideration to the Jacksonian dictum, that negative lesions cannot give rise to positive symptoms except by way of release of function. Of the erudition of the author, and his patient and painstaking examination of a wealth of pathological data, this monograph furnishes ample evidence.

(2) DAS MENSCHLICHE GEHIRN.

Fourth to eighth edition. By Dr. R. A. PFEIFER. With 111 illustrations. Leipzig: Wilhelm Engelmann. 1923. Pp. 157. 9 gold marks.

Dr. Pfeifer's book has reached a circulation, since its first appearance in 1911, of 10,000 copies apparently. It is a curious compilation. Since the presentation of the subject is "gemeinverständlich dargestellt," we can only suppose that the intelligent laity of different countries differ in what they are able to absorb or assimilate. Frankly, the work is a medley of anatomy, physiology, clinical neurology, neuropathology, and psychology, ranging from descriptions of cerebral cytoarchitectonic structure to discussions of the mirror-writing of Michael Angelo, and touching *en passant* on microcephaly, parapraxia, the localisation of the macular system in the calcarine area, and other topics that the professional reader might be forgiven for regarding as "caviare to the general." However, there it is. There are not a few matters of general neurological interest in the volume, but how far they can be appreciated by the non-technical student is an open question. The value of many of the illustrations would be enhanced if their background were white instead of black.

(3) DIE FUNKTIONEN DES STIRNHIRNS.

Ihre Pathologie und Psychologie. By ERICH FEUCHTWANGER, Munich. Berlin: Julius Springer. 1923. Pp. 194. $2.90.

THIS monograph is based on the examination of some 200 cases of frontal lobe lesions occurring in soldiers as the result of gunshot wounds. By way of useful comparison, 200 cases of gunshot wound of the head in which the frontal lobes were, as far as could be ascertained, definitely intact, have been selected for analysis on the lines utilised in the case of the frontal group. A number of special cases are chosen for detailed description. Material of this kind obviously is of much value for elucidation of the manifold problems presented by the subject of the functional significance of the frontal lobes. On general grounds, however, gunshot wound cases are not ideal, especially when the matter of commotio cerebralis is considered; the author has done his best to meet this criticism by the above-mentioned comparison, yet it is not thereby dispelled. We should have liked rather more information on the purely neurological side—e.g., in reference to reflexes—concerning which few details are vouchsafed the reader. By far the greater part of the book is taken up, as is natural, with the disorder of higher functions revealed in frontal lobe cases. Among the general conclusions derived from his study the author indicates that perception, memory, and thinking are less impaired than the functions on the affective side;

disturbances of mood and emotion are common, as is impairment of attention, of "seriousness," and of capacity for appreciating the æsthetic, ethical, and religious aspect of things. Notable interference with the "will-to-act" characterises many cases in the author's group; there is lack of spontaneity, aboulia; the "urge" to act fails; hence the condition often results in what the patient's friends indicate as a change in "character" and "temperament." How far such defects of function are localisable is matter for discussion. It is to be regretted that there appears to have been little systematic search for apraxic phenomena. Certain conclusions in reference to the association of the frontal lobes with the function of equilibrium seem to be open to another interpretation than that given by the author.

(4) The Nervous System.

Introduction to the Histology and Histopathology of the Nervous System. By Dr. Paul Schroder, Professor of Neurology and Psychiatry in Greifswald. Translated from the second revised German edition by Baldwin Lucke, M.D., Assistant Professor of Pathology, University of Pennsylvania; and Morton McCutcheon, M.D., Instructor in Pathology at the University. With 53 illustrations. London: J. B. Lippincott Company. 1924. Pp. 161. 15*s.*

As its name implies, this slender volume is no more than an introduction to a part only of neuropathology—viz., its histological side. It deals on general lines with the normal histology of the nervous system and the deviations from the normal seen in respect of nerve cells, fibres, glia, and mesodermal tissues. Controversial topics are largely avoided, the presentation being semi-dogmatic. Knowledge of these changes in nervous units is an essential preliminary to any study of neuropathology as a whole, and therefore a clear account of their nature will be found useful. Further details might have been furnished by the author in the matter of the plasma cell, the protagon granules of Reich, the multinucleation of cells (glial, Purkinje, &c.)—to mention only one or two points that suggest themselves. The book, nevertheless, conveys in small compass practical information that has often to be sought in individual monographs and scientific papers, and deserves a place on the bookshelf of the neuropathologist.

Intranasal Surgery.

By Fred J. Pratt, M.D., F.A.C.S., and John A. Pratt, M.D., F.A.C.S., Assistant Professors, Eye, Ear, Nose, and Throat Medical School, University of Minnesota. Philadelphia: F. A. Davis Company. 1924. Pp. 334. $5.00.

As far as surgical operations are concerned, the authors of this book have confined themselves very strictly to intranasal surgery. Except that of injection of paraffin into the bridge, no operations on the nose or its accessory cavities are described which involve any access to these regions other than through the nares. This limitation necessarily makes the account of the surgical treatment of many conditions very incomplete; it excludes, for instance, external operations on the maxillary antrum and frontal sinuses, and the surgery of the malignant neoplasms of the nose. In these circumstances it is a pity that any space has been wasted by including such a very inadequate account of malignant disease. Many conditions are mentioned, the treatment of which is only surgical to a very small extent; thus, atrophic rhinitis is accorded considerable space, but the only surgical treatment given is Beck's proposal to insert small splinters of bone under the septal mucous membrane, and no reference is made to the operations devised by Wittmaack, Lautenschläger or Hinsberg. On the other hand, many common intranasal procedures are not described in sufficient detail to be of use to the novice; the removal of polypi is not described at all, and the only reference to their treatment is that "once drainage is established and the discharge stopped, the polypi quickly disappear." Beside a method of intranasal exenteration of the ethmoid, the only operation discussed with full detail is that of resection of the septum, which occupies 50 pages, and is excellently written; the authors leave the greater part of the triangular cartilage to prevent "flapping," cutting it if necessary to make it lie straight. But we regret that they utter no warning against too indiscriminate operating on the septum. Some of their remarks are such as unintentionally to encourage the beginner in this direction; thus they state that "a deflected or thickened septum is probably the beginning of nearly all the troubles within the nose," and again, that most hay fever patients have deflected or thick septa, and that operative interference, to straighten up and thin the septum, together with establishing sinus drainage if necessary, will cure or greatly relieve many cases of hay fever. Undoubtedly, the cure of a definite or severe nasal obstruction will often relieve hay fever; but how often the resection of a slighter deflection or of a small spur fails to bring relief and how few septa are absolutely straight.

The book is profusely and well illustrated, and the anatomical plates are excellent.

Radium, X Rays and the Living Cell.

Second edition. By Hector A. Colwell, M.B. Lond., D.P.H. Oxon., Assistant Radiologist, King's College Hospital; and Sidney Russ, D.Sc. Lond., F.Inst.P., Joel Professor of Physics, Medical School, Middlesex Hospital; Fellow of University College, London. London: G. Bell and Sons, Ltd. 1924. Pp. 365. 21*s.*

The application of radium and X rays to biology is a matter of great theoretical and practical importance and of proportionate difficulty. As so often happens in the growth of a new science, the modest amount of exact knowledge which we possess has become diluted with so large a volume of imperfectly observed facts and ill-regulated experimental data that it is difficult for anyone but the expert to sift the grain from the chaff.

Dr. Colwell and Prof. Russ have come to the rescue, and in their excellent book have presented the accepted teaching with skill and fairness. This, the second edition, has been revised, and contains in a new chapter a summary of facts and theories which will be of particular interest to those working on the subject.

Clinical Diagnosis by Laboratory Methods.

Fifth edition. By James Campbell Todd, M.D., Professor of Clinical Pathology, School of Medicine, University of Colorado. London and Philadelphia: W. B. Saunders Company. 1923. Pp. 762. 28*s.*

Two qualities are demanded above all others of the compilers of manuals such as this: first, the power of clear expression, and secondly, that of discrimination. Nowadays a new volume of clinical pathology seems to blossom forth almost daily, and nowhere does the tree of knowledge produce them in more riotous profusion than in the United States. That Prof. Todd combines a singularly clear manner of expressing himself with a flair that amounts almost to genius for what to include and what to omit makes his work particularly noteworthy; it is already well known in this country, and the present edition will certainly add to its popularity. Much new material has been added, a certain amount has been judiciously eliminated, and the result is a thoroughly satisfactory manual.

The book includes within its scope all the departments of laboratory diagnosis, and that the author has been able to compass what he wished to say within the covers of a volume of such reasonable size and cost depends upon a remarkable judgment for what to omit. No methods of merely academic interest are included, but details are given of almost every technique of approved value. The section on bacteriological methods would have been more complete had the author included a few lines on the use of porcelain filters; the opacity tube method of standardising vaccines might certainly have received mention, and where so many other media are described it was a pity to omit a simple one, such as A. Fleming's, for growing the bacillus of Pfeiffer.

Prof. Todd describes himself as Professor of Clinical Pathology. This is a chair unknown to the seats of medical learning in this country, and it would probably be well that it should continue so; none the less, the schism of "clinical" pathology from the ordinary kind has some sort of justification if it can produce men who can write such useful books as this. The illustrations deserve special mention; the coloured plates are among the best ever produced in a book of this sort and reflect great credit upon the artist, Mr. John W. Rennell, and upon the engravers and printers.

AMBROISE PARÉ.

Selections from the Works of Ambroise Paré. With short Biography and Explanatory and Bibliographical Notes. By DOROTHEA WALEY SINGER. Medical Classics Series. London: John Bale, Sons, and Danielsson, Ltd. 1924. Pp. 246. 12*s.* 6*d.*

ALLOWING that there is a necessity for yet another book about Paré, there could not be a better volume than the one before us. Mrs. Singer has given us Book XI. from Johnson's translation of 1634, together with The Apologie and Voyages into Divers Places, and the Surgical Aphorisms and Rules. She herself has contributed a learned though readable introduction, together with many informing notes upon various statements in the text. Book XI. deals with the nature of gunshot wounds and with the treatment of the same, and draws a comparison between them and the effects of lightning. Paré also combats the popular opinion that gunshot wounds are poisoned. He gives sundry illustrative cases, amongst which the most remarkable is that of Philip de Croy (p. 117 et seq.). On p. 181 we meet with the word "bavin," which Mrs. Singer explains in a footnote as a faggot, and adds that the word was still in use in the nineteenth century. It is rare, however, and the best known instance is in Browning's grim poem, The Heretic's Tragedy, "Good sappy bavins that kindle forthwith." The Aphorisms are given in the original French together with Johnson's translation, which in one instance at least is wanting, for he translates—

> "De toute beste venimeuse
> La piqueure est fort dangereuse"

as "The wounds made by all venemous (*sic*) creatures are dangerous." A study of Mrs. Singer's excerpts ought to lead many readers to explore the original works of Paré.

PEDIATRIC NURSING: ITS PRINCIPLES AND PRACTICE.

By BESSIE INGERSOLL CUTLER, R.N., Instructor in Pediatric Nursing and Supervisor of Pediatric Department, University of Minnesota, Minneapolis. New York: The Macmillan Company. 1923. Pp. 478. 14*s.*

THIS volume, which the author claims is written primarily for the student nurse, seems to cover the whole subject of children's nursing most thoroughly. No claim is made to originality, and much is acknowledged to be borrowed from the text-books of well-know American authorities, numbers of references being given. All must warmly agree with the author's conviction that the main qualifications of a good pædiatric nurse must be a love for children and the ability to get on with mothers. Knowledge of the mental and physical hygiene of children, an acute power of observation, and a faithfulness to detail are essential but secondary. The chapter on growth and development is filled with useful information and statistics. The account of the general conduct of a hospital ward gives one an insight into the elaborate care devoted in the U.S.A. to the children's ward. Certainly, there are hospitals in the British Isles which embrace more than a part of the equipment and conveniences which the author regards as essential. Probably the most useful chapter is that on the care of the premature infant, and the nutrition of infants and children, with recipes for various modifications of food for infants, is well discussed. A chapter is devoted to the special nursing procedure required for certain diseases peculiar to infants and children. A number of surgical conditions are included. The nursing of infectious diseases and orthopædic cases is not omitted.

The book is likely to be widely read and appreciated in this country.

THE CARE AND CURE OF CRIPPLE CHILDREN.

By G. R. GIRDLESTONE, F.R.C.S. Eng., and Mrs. HEY GROVES. Bristol: John Wright and Sons, Ltd. 1924. Pp. 88. 2*s.* 6*d.*

IN the first part of this little work Mr. Girdlestone presents a description of the national scheme for the welfare of crippled children which has been evolved by the Central Committee for the Care of Cripples. In the labours of this body Mr. Girdlestone has taken a distinguished share, and in conjunction with Sir Robert Jones—who contributes an eloquent foreword to the book—he has on previous occasions outlined the essentials of an effective organisation for dealing with cripples. The scheme is based on the establishment in any given area of (1) a central "hospital school" of the open-air type, specially equipped for reconstructive surgery, where the child can be retained for long periods and receive both treatment and education; (2) a chain of after-care clinics in small centres in the area served by the hospital, which makes possible the regular supervision of all children who have been discharged. It must now be well known how efficiently this scheme is already working in Shropshire, where it was first inaugurated, and in Oxfordshire, Berkshire, and Buckinghamshire, under Mr. Girdleston himself. Part II., for which Mrs. Hey Groves is responsible, forms a year-book of hospital schools and other institutions dealing with crippled children, and represents a most useful compilation by an indefatigable worker in the cause of the crippled.

This book is a most important piece of propaganda on a subject which is admittedly of great national importance. It is certain to be read with pleasure by everyone already interested in the problem. We hope that it will find its way above all to the general practitioner of medicine, whose interest and coöperation are so urgently needed if this work is to go forward.

CLINIQUE MÉDICALE DE L'HÔPITAL BEAUJON.

By CH. ACHARD, Professor of Clinical Medicine in the Faculty of Medicine of Paris. Paris: Masson et Cie. 1923. Pp. 457. Fr.25.

THE clinical method, when all is said and done, will ever make its appeal to the medical man. Nothing can take the place of a clinical demonstration, conducted with insight, knowledge, and real acumen. The disadvantage of all books containing a clinical record, however, is that the reader may fail to recapture the elusive fascination attending the actual presentation of patients and the unravelling of a case before the eyes of the onlookers. Occasionally such books become positively tedious in their efforts to reproduce an "atmosphere" by literalness of transcription. Prof. Achard's compilation, we think, achieves a happy mean. Clinical presentations are brief and utilised mainly as an introduction to informative discussions of the points raised thereby. He shows himself a master of clinical medicine, and we are especially attracted by the able neurological essays dealing, inter alia, with diphtheritic paralysis, pontine paralyses, the hemianopias, certain complications of tabes, and dissociation of the oculo-sympathetic syndrome.

Reports and Analytical Records.

" MIRA " : HUNGARIAN MEDICINAL WATERS.

(MEDICINAL AND APERIENT WATER SPRINGS CO., LTD., BUDAPEST.)

THREE of these natural waters have been submitted to us for examination : " Mira " (1), a natural aperient water ; " Mira " (2), a natural medicinal water ; " Mira " (3) (Baby), a natural laxative water for children. When analysed we found these waters to have the following composition expressed in grammes of saline constituents per litre :—

—	Mira 1.	Mira 2.	Mira 3.
Total saline matter	55·11	23·9	14·8
Chlorine (Cl)..	2·34	2·62	2·52
Sulphuric acid (SO_3)	30·05	10·91	5·80
Lime (CaO)	0·50	0·70	0·34
Magnesia (MgO)	3·90	1·72	0·60
Soda (Na_2O)..	18·12	7·60	5·42
Silica (SiO_2)	0·10	0·20	0·12
Iron and alumina (Fe_2O_3 and Al_2O_3)	0·10	0·15	—
Potassium, lithium, strontium, &c. ..	Traces	Traces	Traces
Specific gravity (water = 1000) ..	1050·6	1020·88	1012·12

The above are probably combined as follows :—

—	Grains per gallon.		
	Mira 1.	Mira 2.	Mira 3.
Sulphate of sodium	2578·1	852·0	515·0
Sulphate of magnesium	817·2	361·2	124·0
Chloride of sodium	269·8	302·6	291·0
Sulphate of lime	85·7	71·4	57·0
Carbonate of lime	—	35·0	—
Silica	7·0	14·0	8·7
Iron and alumina	7·0	10·5	—

These analytical results show that the aperient water (No. 1) consists mainly of the sulphates of sodium and magnesium. It is well known that a water of this type is of general application in disorders of metabolism and elimination such as constipation, auto-intoxication arising from over-indulgence in rich foods, alcohol, &c., pyorrhœa of the gums, and a number of skin diseases, such as boils, nettle-rash, and eczema. The water is said to be mild and gentle in its action.

Mira (2), the Glauber salt medicinal water, is not so strong as No. 1 and, moreover, the ratio of magnesium sulphate to sodium sulphate is greater than in Mira (1). The action of this water is said to be milder than in Mira (1), and it is, in consequence, more adapted for chronic cases in which a prolonged course of the remedy is indicated. It is claimed that the water is suitable for the treatment of cases such as commonly resort to Carlsbad and Marienbad.

Mira (3) is a water in which the principal saline constituents are sulphate of sodium, chloride of sodium, and magnesium sulphate. The water is a useful laxative for children in cases where the ailments are connected with errors in diet. During dentition a few doses of this water relieve congestion of the gums, and in febrile conditions it may be used with advantage.

Our analyses are not in all respects in very close agreement with the figures quoted on the labels, but this is not to be wondered at as natural waters of high mineral content tend to vary somewhat in their concentrations from time to time.

(1) SACCHAROMYCIN ; (2) EVATMINE.

(BRITISH ORGANOTHERAPY CO., LTD., 22, GOLDEN-SQUARE, LONDON, W. 1.)

(1) Saccharomycin is described as an active isotonic and isothermal-living yeast for which the producers guarantee that its vitality will continue indefinitely and undiminished in the ampoules in which it is supplied. Preparations of yeast, it is well known, have yielded good results in staphylococcus infections, acne, and furunculosis, while a serum obtained from animals fed on enormous quantities of brewer's yeast has been used to introduce the active principle in concentrated form. In acne fresh brewer's yeast has been successfully employed, but the smell and taste of yeast, and its tendency to cause gastro-intestinal disturbances, such as diarrhœa and flatulence, have proved drawbacks to its use. It is claimed for saccharomycin that the disadvantages of brewer's yeast are avoided, while it is activated at body temperature and so is able to retain its potency. In cases of furunculosis and acne one ampoule of the preparation may be taken daily before breakfast accompanied by syrup and water, according to precise directions supplied. The price per box of 6 ampoules is 10*s.*

(2) Evatmine is compounded of the active extract of the posterior lobe of the pituitary ⅞ gr., adrenin solution (1 : 1000) 8 minims, physiological salt solution 8 minims, and has been used for some time both in this country and especially in France for the relief of asthma, and in the treatment of persistent cough, croup, and other spasmodic affections. While adrenin and pituitary extract, both of which have been used in these affections, have not been attended with consistent results, certain French observers state that a suitable combination of the two substances produce reliable effects. The quantity of pituitary extract in evatmine while sufficiently large to secure therapeutic action is so small that adverse reaction is unlikely or impossible, while the adrenin content of an ampoule of the compound is half the usual quantity of the drug administered as a dose. The preparation is administered by slow subcutaneous injection, it sometimes being necessary to give a second injection at an interval of half an hour ; in extreme cases a third injection may be made, but not more than three injections should be given over a period of 24 hours. As a prophylactic in asthma one injection is given daily or on alternate days for from two to four weeks. From one-half to one-eighth of the adult dose (1 ampoule) is given to children under 14 years of age according to the number of years. The price of a box of 6 ampoules each of 1 c.cm. is 12*s.* 6*d.*

The company's products are supplied to the medical profession, and are obtainable by the public only upon the presentation of duly signed prescriptions.

KALZANA.

(JAMES G. CLARK, 71, HIGH HOLBORN, LONDON, W.C. 1.)

This prescription, which is identical with albulactin, is made by Messrs. Wulfing and Co., of Amsterdam, and is put by the British agent on the London market in flasks of 75 tablets, each tablet containing 7½ gr. of calcium sodium lactate. The double salt is a standard preparation of calcium, and the combination is extremely soluble and easy of absorption. The therapeutic value of calcium is quite well known to all medical men, and both its chemistry and its chemical results have been demonstrated by sound authorities. Kalzana has been employed with good results in hospital and private practice, the claim being made that by its use calcium retention is effected by the addition of sodium lactate. The tablets may be taken in a little water or milk ; crushing with a spoon will hasten disintegration. They may also be simply masticated, and are best taken after meals. To small children and infants they should be given well powdered and dissolved in milk.

To obtain the benefit of the drug for purposes of ordinary nutrition one or two tablets can be taken daily, but the same dose or three tablets can be taken three times a day where a special addition of lime to the diet is required, as in the case of nursing mothers. Children subject to troubles of dentition attributable to a deficient amount of lime in their food may take one or two tablets daily.

THE LANCET.

LONDON: SATURDAY, MAY 10, 1924.

INFANTILE ATROPHY.

The problems of infantile atrophy form the subject of the Goulstonian Lectures delivered this year by Dr. Leonard G. Parsons, and published in recent issues of The Lancet, his final lecture appearing in another column. Although in his introductory address the lecturer described his subject as lacking in general interest, if not indeed threadbare, it is one which has exercised the minds of the public and the profession for so long, and its importance is so great both from private and national points of view, that many readers will welcome the admirable exposition which Dr. Parsons commences thus modestly. From the seventeenth century onwards the wasting diseases of children have produced a series of important studies by British physicians, often illuminating, but always inconclusive as regards the ultimate explanation of these phenomena. At the present time it is perhaps the work of the German school of pædiatrics, and particularly the views of Czerny and Finkelstein, which have chiefly influenced the profession. Czerny emphasised the view that wasting is a disturbance of growth and general nutritional function rather than a disease per se, and that it occurs in certain predisposed children when subjected to certain types of feeding or to infections, the children particularly predisposed being those whom he described as suffering from the "exudative diathesis." Amongst the immediate exciting causes he particularly stressed two: one in which overfeeding with milk led to an intolerance for fat, and a second in which excess of starch caused acid diarrhœa or carbohydrate œdema. Protein he considered relatively innocuous, thus adopting a view entirely opposed to those of earlier observers such as Biedert and Eustace Smith.

These theories, for it cannot be claimed that any exact scientific basis has yet been established for them, have certainly been useful in removing much prejudice, but they have more recently been supplanted in many minds by those of Finkelstein. Like Czerny, this observer considered fat and carbohydrate as factors of greater potential danger to the infant than protein can be, but he also proposed the theory that injury to the cells of the intestinal mucosa by the salts present in whey was of high importance, a theory which has been largely disproved by the subsequent work of Woodyatt and others. Classifying his cases according to the weight-chart of the infants, Finkelstein divided them first into those where there is excessive fat, producing disturbance of balance in the carbohydrate-fat ratio, and secondly those in whom carbohydrate-tolerance was slight. From one of these initial categories the wasting child was liable, if untreated, to pass into the more serious ones of (*a*) decomposition (marasmus), or (*b*) intoxication. From these suggestive theories the Goulstonian lecturer passes to a survey of the mass of biochemical research which has been carried out in this country and in the United States during the past few years. Reviewing the figures given by Hutchison, by Utheim, by Holt, and in his own extensive series, concerning the digestion and absorption of fat in wasting infants as measured by analysis of the fæces, Dr. Parsons reaches the important conclusion that digestion of fat is usually efficient, and, in the absence of diarrhœa, absorption of fat is satisfactory, the two conditions under which fat indigestion may become the cause of atrophy being (1) the development of diarrhœa, and (2) the giving of high fat-content dried milks. It will thus be seen that careful laboratory work in this country, as in the United States, has failed to support the supposed scientific basis of the theories of the German authorities. In his second lecture Dr. Parsons deals with other nutritional factors, many of which have as yet been very imperfectly studied. His remarks on the possible mechanism of the effects of vitamin deficiency are highly suggestive. Cramer, Lumière, Gross, and others have shown that when young animals are fed on diets deficient in vitamin A an acceleration of the passage of food through the alimentary canal occurs, and that this diarrhœa is accompanied and perhaps explained by an atrophic process affecting the intestinal mucous membrane. It may well be that herein lies the explanation of the pseudo-diarrhœa of many atrophic infants, and it is to be remembered that it is the animal whose diet contains excess of carbohydrate as well as deficiency of vitamin A which shows the most marked symptoms in these cases. In a later passage the lecturer wisely emphasises the importance in dietetics not only of the quantity, but of the quality of the protein food. Many writers upon the subject of infant-feeding, even at the present day, are prone to neglect the possibilities of errors arising from this cause. Protein is a loose term in contrast to such headings as carbohydrate and fat, for it is the amino-acids, derived from the native proteins, which are the ultimate units from which the body must build its tissues, and individual proteins differ considerably from one another in their content of various types of amino-acid. Thus Holt has shown that lactalbumin, which is present in human milk in far greater proportion than in cows' milk, is richer in leucin, lysin, and tryptophane than is casein, and it is readily conceivable that a diet rich in total protein may be actually deficient in one or other of these essential amino-acids. Again Moro, Bauer, and Lust have all shown that in certain infants there is an intolerance to cows' milk apparently due to the absorption of certain foreign peptones. On these grounds, and in the light of his personal experience, Dr. Parsons finds that the protein of the diet may be by no means so unimportant as the German workers have argued.

Clearly we are still far from reaching final knowledge concerning the causes of infantile wasting, but for the present the list given by Dr. Parsons is both of practical utility and in accord with the known scientific facts. He classes the causes as follows: (1) Insufficient food, with pyloric stenosis as an occasional causal agent; (2) unsuitable food—artificial foods with excesses or deficiencies of one or more factors being the common causes in this group; (3) diarrhœa and vomiting; (4) infections such as pyelitis and pneumonia; (5) unsuitable hygienic surroundings; and (6) pre-natal and constitutional causes. It may be said that in the vast majority of cases the cause is to be found in the early groups, and should usually be preventable. To what extent infantile pyloric stenosis is preventable remains an unanswered question. Dr. Parsons holds the view that these cases are truly a congenital disorder, but whilst the majority of observers incline to this opinion it is at present still an unproven conjecture. Happily, this uncertainty of ætiology is counterbalanced by a most pleasing improvement in the recent results of treatment, and Dr. Parsons's highly successful series of cases treated by Rammstedt's operation bears out the experience of many others; few cases could be more desperate than are many of these when first treated, and the brilliant results of the modern treatment are a further triumph for the abdominal surgeon. Post-operative treatment of these cases remains difficult, and Dr. Parsons has experienced the same dangerous tendency to diarrhœa in these infants that other observers have recorded. This he believes to be due to the failure of a starved intestine to deal with the newly arrived food-supply rather than to any pancreatic deficiency, its frequent occurrence, together with the long continuance of atrophy even after operation in other cases, being evidence of how slow and precarious may be the recovery of the organism from a nutritional disturbance, when such a disturbance has been present for some time. There comes, indeed, a point in all such cases where the general metabolic upset is so grave that it is doubtful whether its correction and the most careful after-treatment can possibly save the patient. It is the importance of early recognition followed by sane treatment that makes the study of this group of infantile diseases so useful both to the profession and the State.

THE ÆTIOLOGY OF CERTAIN LESIONS OF THE SKIN.

The appearance of a new edition of Dr. Darier's Précis[1] is an event of the highest importance in the dermatological world, for, since the first edition was published in 1908, the book has stood alone. The work of a master, it possesses an individuality and a charm that at once raises it above the level of other text-books of dermatology, and the reviewer has never forgotten the advice given to him many years ago by one of the wisest of English dermatologists—to buy the "Précis" and make it his bible. Those who are privileged to claim personal friendship with the author can readily understand wherein lies the virtue of his book. Other dermatologists have, perhaps, done more original work, but no one has a more profound knowledge of his subject or a greater breadth of view, and with these is combined a literary style of a high order. The arrangement of the subject-matter, which was adopted in the original edition, remains the same, and it could hardly be improved upon. The book is divided into two parts. In the first the various eruptions and non-eruptive abnormalities of the skin are considered according to their *morphology*, so that we have chapters on the erythemata, urticaria, eczema, erythrodermias, papular, nodular, vesicular, bullous, pustular, and ulcerative eruptions, dyschromias, atrophies, hypertrophies, and affections of the follicles, hair, nails, and sweat glands. In the second part the definite diseases of the skin are dealt with—"the morbid entities of known ætiology, classified according to the nature of their causation"—such as the dermatoses produced by external irritants and the drug eruptions, the parasitic diseases, the pyodermias, the bacillary and protozoal infections, and the dermatomycoses; in this part, too, are included the various tumours of the skin, and what Leredde has termed the "hæmatodermias"—i.e., the eruptions associated with the leukæmias, Hodgkin's disease, and mycosis fungoides. This arrangement is simple and logical, in marked contrast with the haphazard classification adopted in many text-books.

The modern dermatologists in France would seem to be almost obsessed by two infections—syphilis and tubercle—and the number of conditions which are ascribed by some of them to latent infection with one or other of these diseases is so great as to be almost ludicrous. Darier himself has recently deplored the tendency of his younger colleagues to concentrate their minds on syphilis to the exclusion of more strictly dermatological problems, but even he, we think, is inclined to exaggerate the importance of tubercle and syphilis and to under-estimate the influence of other chronic infections in the ætiology of eruptions of doubtful origin. This question arises chiefly in connexion with the rather heterogeneous group of eruptions which in 1896 Darier classed together under the term "tuberculides"; in this group he included lichen scrofulosorum, papulo-necrotic tuberculides (folliclis, acnitis, &c.), the various forms of sarcoid, lupus erythematosus and lupus pernio, and the erythema induratum of Bazin. Other authors have since, with little justification, attempted to enlarge the group by including such conditions as erythema multiforme, pityriasis rubra pilaris, the pityriasis rubra of Hebra and Jadassohn, angiokeratomata, and certain forms of parapsoriasis. On the other hand, it would appear from the work of Landouzy and others that erythema nodosum, though probably, as a rule, a manifestation of rheumatic or streptococcal infection, may be a true tuberculide. Moreover, the researches of Jadassohn and his pupils, and more recently of Bloch, have shown that in cases of deep trichophytosis there may occur a variety of toxic eruptions—trichophytides—which are morphologically similar to some of the above; they include a follicular eruption resembling lichen scrofulosorum or lichen spinulosus, an erythema scarlatiniforme, an erythema multiforme, and an erythema nodosum. With regard to lupus erythematosus, although a clinical association with active tuberculosis and the results of experimental animal inoculations point to it being in some cases a tuberculide, there is conclusive post-mortem and other evidence that it is not always so, and even folliclis and erythema induratum, though in many cases undoubtedly tuberculides, may, as the experimental observations of Guy would suggest, in certain patients be produced by embolism with organisms other than the tubercle bacillus. The question is reviewed and discussed by Darier, and he now proposes to substitute for the term "tuberculides" that of "tuberculoides," for he concludes that these eruptions represent a syndrome, which can arise from various causes, and that, although tuberculosis is the commonest ætiological factor, other infections, particularly syphilis, may give rise to them. He says that the work of Ravaut, Tzanck and Pelbois, and Pautrier, as well as his own observations, have proved beyond doubt that the complete clinical picture of the tuberculides can be produced by syphilis, and that in this case the Wassermann reaction is frequently positive and anti-syphilitic treatment has a remarkable therapeutic effect. This is particularly true in certain cases of hypodermic sarcoids, erythema induratum, disseminated nodular sarcoids, sarcoid of Boeck, papulo-necrotic tuberculides, and even of lupus erythematosus. Darier remarks in this connexion that an immediate differential diagnosis between lichen scrofulosorum and a follicular syphilide is often impossible.

With this attitude of mind many English dermatologists will find themselves in disagreement. Quite recently Dr. H. G. Adamson has argued that of the enormous number of different cutaneous eruptions that we recognise, each has its own distinctive features—for example, the morbilliform rash of measles, the rose spots of typhoid, the eruptions of scarlet fever, of chicken-pox, of secondary syphilis, of lichen planus, of pityriasis rosea, of psoriasis, &c. And he points out that when we *do* know the cause of a cutaneous eruption, which has its own individual character, we find it to be due to a specific causative agent, such as the typhoid bacillus, the tubercle bacillus, or the *Treponema pallidum*. Is it not therefore logical to suppose that in other equally distinctive eruptions there must be a specific causal organism for each one? Now this is a very suggestive argument and merits every consideration, but it seems to us that it may be pushed too far. No one can doubt that pityriasis rosea, for example, is a distinct entity due to infection with a specific organism as yet undiscovered. The same is true of the exanthemata, and probably of lichen planus. But certain eruptions, equally distinctive as regards their clinical appearances, are certainly not distinct entities from an ætiological standpoint. Urticaria and eczema, for example, may be due to a variety of causes both external and internal. Erythema nodosum, like erythema multiforme, with which it may be associated, is certainly in some cases due to infection with a streptococcus. Yet, as has been said, it would in others appear to be a tuberculide or a trichophytide. Again, it is difficult, in view of clinical and experimental evidence, to deny that lupus erythematosus is sometimes a tuberculide, but there is equally conclusive evidence that it may be a manifestation of acute or chronic streptococcal infection. It would also, we repeat, appear likely that the various papular and nodular necrotic lesions, which are in most cases rightly considered as tuberculides—i.e., inflammatory reactions around emboli of tubercle bacilli carried to the skin or subcutaneous tissue from some distant tuberculous focus—may also be provoked by emboli of other organisms. They occur only in persons of a definite type with a feeble peripheral circulation, and in these subjects there is no reason why a chronic bacteriæmia with any infective organism should not give rise to them.

---

[1] Précis de Dermatologie. By J. Darier. Third edition. 1923. Paris: Masson et Cie. Pp. 996. Fr.50.

To sum up, although with Dr. Adamson we deplore the tendency manifest in some quarters to neglect accurate clinical and histological observation, and vaguely to ascribe widely different eruptions to latent syphilis, tubercle, or focal infection on quite insufficient grounds, there is no question that certain forms of eruption are merely cutaneous reactions which may be provoked by various infective organisms, and it is only by exhaustive investigation in each individual case that the actual cause of such an eruption can be determined.

VERTIGO AND FEAR.

An article by Dr. W. F. Menzies in our present issue, showing that what we call vertigo should be considered as a combination of physiological and psychological processes, opens up many vistas, like every approach to the problem of body and mind, and introduces a subject of immediate clinical interest. Of the five processes which he describes as resulting in vertigo, three—the peripheral stimulus, the vestibular stimulus, and the response from plain and striped muscle, are physiological; the next process—emotion, belongs more to the sphere of psychology, though the Lange-James theory expresses it in physiological terms, and the last—the realisation of the emotion in consciousness, is only expressible as a process of mind. Dr. Menzies is, perhaps, restricting himself to one part of a problem when he decides that emotion is excited in order that awareness of the danger of falling may be aroused in the organism, vertigo arising only as an emotional outflow of instinctive fear. That other bodily disturbances besides those causing vertigo can induce a state of fear is illustrated by Sir Clifford Allbutt's note in our issue of April 26th, in which he describes a sufferer from pulmonary thrombosis as having "the appealing look of a man in dread," though there was present neither pain nor dyspnœa. A process which resulted in fear was initiated by the physical condition, and one can conceive some of the concomitants of vertigo—the anxiety, nausea, sweating, chilliness, and final collapse—as likewise indicating the presence of fear rather than as part of the primary symptoms. But that the fear should be specifically related to the danger of falling does not seem so certain. Fear is not necessarily a concomitant of vertigo, and Dr. Menzies gives examples of vertigo without fear. That produced by inhaling the smoke of the morning cigarette is, we may assume, not unpleasingly fearful (it may be observed that a modicum of fear is to some people a desired sensation); the vertiginous bricklayer who freely mounted ladders had certainly divorced the emotion of fear from his subjective troubles. Children, moreover, find enjoyment in inducing vertigo, though many adults find anything but pleasant an attempt to return to the childish pleasure of the swing. Actual danger of falling is not often followed by the syndrome, and the beginner on horse or bicycle may be fearful in the extreme but experience no vertigo.

It appears that Dr. Menzies's separation of processes might be carried still further; on the one side are the stimulus and its perception qua stimulus, and on the other are the results of that perception showing themselves in many and varied unpleasing sensations with their bodily accompaniments; and this separation has its clinical counterpart inasmuch as one group may occur without the other. This leads us to the question of definition, and we are compelled to ask which of the groups is indicated by "vertigo." The same question presented itself to Bonnier, who wrote [1]: "One can say, it seems, quite safely, that vertigo seems to be a complex disturbance which appears on the occasion of a sensation or illusion of movement or falling; and inversely, when it appears for any cause whatever, it is accompanied, among other symptoms, by an illusory sensation of movement or falling." This suggested reversibility is shown in those nervous patients in whom vertigo accompanies or takes the place of an attack of pathological fear. Even in healthy people the vertigo that occurs on heights can hardly be expressed in any other sequence than one in which apperception of danger occupies the first place. Although Dr. Menzies compares his with the Lange-James theory, which, by the way, is far from generally accepted by psychologists, yet it must be noted that the latter theory does no more than express the mode in which the apperception of danger produces those bodily changes upon which the emotion depends. A child on a railway track may perceive an approaching train without any Lange-James reaction if the danger is not recognised. In such a case as that described by Sir Clifford Allbutt the gross pathological state may well have induced a sense of impending disaster which in its turn set up the train of bodily changes resulting in the emotional state of the patient; and this sequence differs from that postulated by Dr. Menzies, in which conscious realisation comes last. It is an extension of the theory to assume that, in the absence of a mental stimulus except as an end-result, bodily processes of themselves can induce a specific emotion. Dr. MENZIES describes a defensive emotion, with adrenalin outflow and the rest, which is registered in the thalamus and thereafter conveyed to the cortex, but in the classical experiments of CANNON and CRILE the cortical stimulus, the apperception of danger, preceded the adrenalin outflow. Whether this reaction is reversible is a matter of clinical importance, and the way in which it is regarded rather sharply separates the school which seeks the explanation of pathological fears primarily in mental processes and that which sees their origin in physical disturbances in which the endocrine organs are probably concerned. Dr. MENZIES has succeeded in raising a problem of considerable interest.

ISOLATION OF THE VIRUS OF FOOT-AND-MOUTH DISEASE.

A RARE example of a reward for steadfast concentration on one problem by one man is to hand in the news that the virus of foot-and-mouth disease has at last been isolated by Prof. Paul Frosch, Professor of Dietetics and Bacteriology in the Königliche Tierärztliche Hochschule in Berlin, working in conjunction with Prof. Dahmer. More than 20 years ago Frosch, working with Loeffler,[1] discovered that a filtrable virus was responsible for foot-and-mouth disease. Frosch has worked at this subject with persistent diligence ever since, and at a meeting of the Berlin Micro-Biological Society on April 7th he was enabled to announce the discovery of a tiny bacillus which he has isolated and from which, we understand, he has been able to reproduce the disease after 13 subcultures. The organism is only 0·1 micron long in its longer axis. It forms minute colonies, on a suitable solid medium, of the diameter of a red blood corpuscle—that is, 7 to 8 microns. This bacillus the two workers generously propose to name *Loeffleria nevermanni*. Prof. Dahmer described at the same meeting how he succeeded in separating the organism from the fluid of the vesicles and in developing a colony on a solid medium. From these colonies the two workers succeeded in making subcultures with which they inoculated a series of guinea-pigs. The guinea-pigs acquired an immunity which was demonstrated in that, after inoculation, the animals showed no generalised foot-and-mouth disease when subsequently infected with virulent material, though the primary vesicles appeared. These experiments were carefully controlled. From the vesicles of these culture-infected guinea-pigs the organism could be further subcultured. From the experiments it was concluded that guinea-pigs infected with culture material were protected from a generalised disease on subsequent reinfection. The principle of the methods whereby what appears to be a very fine piece of research was achieved bears a curious resemblance to that which gave us insulin. In both cases the problem was that of getting rid of a substance which had a destructive effect on the material to be isolated. It has long been known that the fluid from the vesicles of infected animals is extremely infective on the first day, considerably less so on the second, and that on the third day its potency appears to be lost. Similarly, if an attempt be made to cultivate this fluid, its infectivity diminishes rapidly. The difficulty was to devise some means of getting rid of the unknown substance which kills off the virus. Frosch apparently took the vesicular fluid and filtered it through a collodion filter, and then was able to wash the organism off this filter and grow it, but the actual technique of the culture process has not at present been disclosed. The investigators are taking steps to have their work confirmed at the Department of Health and at the Robert Koch Institute. The economic value of this discovery, if, as seems likely, it will be confirmed by subsequent workers, will be really immense. We await further information on the subject with the keenest interest.

Annotations.

"Ne quid nimis."

UNLIMITED INDEMNITY.

THE following letter has been sent to all registered medical practitioners in England, Wales, Scotland, and Ireland by the two great Defence and Protection Societies, and, it will be seen, that these bodies have now decided to offer an unlimited indemnity to their members who may be mulcted in legal damages:—

30th April, 1924.

DEAR SIR OR MADAM,—Recent events have emphasised the extreme importance of every member of the profession being adequately protected in the performance of his duties.

Medical practitioners are reminded of the advantages attaching to membership of one or other of the above-named societies. Members of either body have the benefit of having their cases considered by an experienced council, as well as of being advised both generally and legally on all matters connected with the practice of their profession. Many claims are immediately withdrawn when it becomes known that the practitioner concerned is a member of one or other society. Every day the secretaries of the two societies are engaged in giving advice to their members without expense beyond their annual subscription.

Members of these societies are not only entitled to ask for assistance in the defence of actions brought against them, but the societies frequently institute actions for the protection of the interests and professional reputation of members.

The councils of the two societies have now decided to afford their members unlimited indemnity against damages and costs of the other side on the same conditions as at present prevail.

Yours faithfully,

Signed on behalf of the
Medical Defence Union, Ltd.,
WALTER G. SPENCER,
President.
SEYMOUR TAYLOR,
Treasurer.
JAMES NEAL, General
Secretary.

Signed on behalf of the
London and Counties Medical
Protection Society, Ltd.,
JOHN ROSE BRADFORD,
President.
CHARLES M. FEGEN, Treasurer
and Chairman of Council.
HUGH WOODS, General
Secretary.

Although this action is obviously a result of the Harnett case, still under adjudication upon appeal, it may be said that hitherto the limit fixed by the Societies concerned has been well outside the amount of any indemnity required and that the ideal of putting no limit to the indemnity has always been aimed at.

THE INDIAN (SUBORDINATE) MEDICAL DEPARTMENT.

WE are informed that meetings of the domiciled European community in India are being held to protest against the circular issued by Indian Army Headquarters regarding the reduction or abolition of the Indian Medical Department, and the Anglo-Indian Association, London, has taken the matter up by requesting the Secretary of State for India, Lord Olivier, to hold an official inquiry on which the Anglo-Indian and domiciled European community should be represented. This department was originally intended to be recruited from the sons of persons of pure or mixed European blood and has had a long and useful career. Its members were originally styled apothecaries and the department afterwards included the hospital assistants. The former were employed with British troops and the latter with Indian units. Something more than a quarter of a century ago the apothecaries were given the title of assistant surgeon and a decade or so later the hospital assistants obtained the title of subassistant surgeon.

---

[1] Report of the Commission for Investigation of Foot-and-Mouth Disease at the Institute for Infectious Diseases, Berlin. See Jour. of Comp. Pathol., 1899, xii., p. 79.

Later still the department—long styled the Indian *Subordinate* Medical Department—lost the objectionable word subordinate, and now, it seems, the department is to go altogether. The assistant surgeons performed the duties of orderly medical officers in British hospitals and carried out not only the duties of wardmasters and dispensers, but many of the less important medical functions of junior officers and all the duties of quartermasters of the R.A.M.C. It is difficult to see how the abolition of the department will effect economy, as in addition to their military duties assistant surgeons were recruited for many civil appointments, while a few obtained British qualifications and entered the Indian Medical Service. Sir Patrick Hehir started his distinguished career in the ranks of the old I.S.M.D.

A MATTER OF TASTE.

OUR attention has been drawn to a signed article in a daily paper entitled "A Parliament of Neurasthenics," wherein a Medical M.P. discusses the alleged nervous condition of his colleagues. He deduces from such mannerisms, neuro-muscular symptoms and vaso-motor instability as his trained observation of Members has detected that many of his colleagues suffer from neurasthenia in some form. With the accuracy of his pathological interpretation of characteristic movements and manners we are not concerned, although it is natural that in legislators dealing with affairs of great moment outward signs should appear of the inward conflict. It has, however, been suggested to us that members of the medical profession would be wise to be at least as discreet in their observations in the House as they would be in a friend's drawing-room. Articles from a tailor who happens to be a Member of Parliament, criticising the cut, materials, and degree of seniority of the clothes of his neighbours, would be open to a charge of bad taste, and it is doubtful whether the estimation of the extent of mental and physical deficiencies on the part of a medical Member is in better taste. Doctors in Parliament have certain privileges granted to them on account of their professional status and ethic which it would be a pity to forfeit.

THE CORRECTION OF SPEECH DEFECTS.

AFFECTIONS of speech, complicating the apparatus concerned in the production of a normal voice, are so various and frequent that, until recently, it has been something of a reproach to the medical profession that facilities for dealing with them have not been more adequately provided. Twenty years ago the routine treatment of functional aphonia was to stimulate the larynx by the internal or external application of the faradic current, or by painting the glottis with a solution of chloride of zinc or some other irritating solution. This often succeeded in restoring the voice for a time, but the aphonia usually soon returned, and with each relapse treatment became more uncertain and the patient more despondent. The modern method consists in obtaining the coöperation of the patient, and in educating him in the proper use of the various groups of muscles concerned, when the result is usually a lasting cure. So, also, many cases of chronic laryngitis and pharyngitis, which are maintained in a vicious circle by improper and excessive use of some of the muscles of voice-production, are amenable to treatment by vocal education. Stammering, as is well known, is curable by similar methods. In addition to these and similar functional disturbances, defects of speech due to physical causes can be greatly improved by educative treatment; such are cleft palate, speech affections due to hemiplegia and to operations about the larynx and pharynx, while the defective speech which results from severe deafness can also be bettered by similar methods. It is, therefore, all to the good that this has now been recognised, and that the speech clinic which has been working at St. Bartholomew's for the last 13 years has now its counterparts at Guy's, St. Thomas's, Great Ormond-street, and the Royal Dental Hospital —we are not sure that the enumeration is complete. There is also a strong medical element in the administration of the Vocal Therapy Fund, which was founded for the restoration of health through speech, song, and correct breathing. Sir Bryan Donkin is chairman of this Fund, and other medical names on the committee are those of Dr. M. Flack, Sir J. Dundas-Grant, Sir Frederick Mott, Dr. C. S. Myers, F.R.S., and Dr. Jane Walker.

THE ARGYLL ROBERTSON PUPIL IN NON-SYPHILITIC CASES.

SPEAKING in the discussion on the Physiology and Pathology of the Pupil Reactions at the Annual Congress of the Ophthalmological Society of the United Kingdom, reported on p. 968, Mr. R. Foster Moore opened up a most important and interesting question —namely, the value of the Argyll Robertson pupil as an indication of past syphilitic infection. We have become so apt to associate this phenomenon invariably with tabes or general paralysis, that it is slightly disconcerting to read Mr. Foster Moore's series of cases in which it occurred apart from any other demonstrable lesion of the central nervous system, and without any possibility of the presence of syphilis. It is true that such cases show slight differences from the typical Argyll Robertson reaction, but these may be difficult to elicit. The most important points to note are, firstly, that what we may call the "false Argyll Robertson" pupil may be present from birth onwards and may be unilateral. Again, in all the cases, the reaction to accommodation, though present, was very sluggish, the accommodative power, however, remaining normal. The whole question is most important and calls for a much fuller investigation of the causes of the true Argyll Robertson pupil. We do not yet know either the actual cause of this or the anatomical site of the lesion, nor is opinion yet unanimous even on the subject of the central paths of the normal pupil reactions. There is a vast field for research here still, and it is to be hoped that neurologists and ophthalmologists will turn their attention anew to the subject of the central connexions of the visual tracts.

MALTA FEVER IN AZERBAIJAN.

RUSSIA has recently been the prey of terrible epidemics, from which nothing can save the country except consistent hygienic administration informed by scientific work. A recent article [1] from the bacteriological laboratory of the State University at Baku is an example of such work. Dr. P. Sdrodovski gives an account of the very thorough investigation he made when he diagnosed a hitherto unrecognised case to be Malta fever, a disease never recognised before in Azerbaijan. The patient, a lady, had been ill for two months with persistent irregular pyrexia, headache, pains in the joints, sweating, and loss of weight. Her spleen and liver were enlarged; she had leucopenia and monocytosis. In September blood culture showed a micrococcus closely resembling *Micrococcus melitensis*, agglutinated by the serum of the patient in a dilution of 1 : 1000. It was found that the patient's mother was also suffering from a similar attack (at first thought to be malaria), and her blood agglutinated this micrococcus (1 : 500). They had become ill almost simultaneously on leaving Perebedil (a village in the Eastern Caucasus a hundred miles from Baku), where they had spent May and June, and where both had drunk much raw goats' milk. At the end of September an expedition to Perebedil was organised to clear up the epidemiology of the disease. The blood of 30 natives with pyrexia was examined, and two (only) were found to agglutinate the micrococcus—one (the owner of the goats, with persisting fever and pains in the ribs) in 1 : 2000; the other (his brother, with persisting fever and swelling of a knee), in 1 : 500. Six of the milch goats were examined; the blood of two gave positive results (1 : 200, 1 : 1500); both looked healthy, the second, in December, was found to have a swelling in the knee-joint of a foreleg. Two other cases were subsequently found in Baku, unrelated in any discoverable way to the others or to Perebedil, which is not, therefore, the only centre of the disease in the country. The organism found was pathogenic to rabbits, 3 of 10 died; of rats, 7 of 10; of mice, 3 of 4 died within three days, and it was deadly for guinea-pigs. Post mortem it was recovered from the spleen and other organs in pure culture. Rabbits showed high agglutination (1 : 10,000) but, like goats, showed no characteristic symptom if the case became chronic. One hundred and fifty other pyrexial cases in Baku were examined, but no other gave agglutination at 1 : 100 dilution. The rabbit serum sent by Dr. Sdrodovski to Hamburg agglutinated standard cultures of *M. melitensis* there up to 1 : 3200, normal rabbit serum being negative.

THE LIMITATIONS OF CHEMICAL ANALYSIS.

THE necessity for rigorous biological testing of drugs such as pituitary extract, insulin, and salvarsan, which has given occasion for a Therapeutic Substances Bill, draws attention to the limitations of purely chemical testing and standardisation in the case of complex drugs of unknown chemical nature. In dealing with pure chemical compounds of known constitution, chemical methods of testing are generally quite sufficient and satisfactory as well as being usually more rapid and simple to carry out than biological tests. But in cases such as pituitary extract and insulin where the chemical nature of the active principle is quite unknown, biological methods are absolutely necessary. In other cases, such as ergot, where several active principles have been isolated and their chemical constitution accurately established, biological methods of testing are still advisable, as no simple satisfactory chemical tests are available for the amount and purity of the chemical components. Salvarsan, on the other hand, is usually regarded as a single pure chemical compound, but it is extremely doubtful whether the ordinary technical product is ever the pure substance represented by the formula assigned to salvarsan. Even if it were, this substance undergoes oxidation so readily that the need for careful testing and control is at once revealed.

The limitations of chemical analysis are rarely sufficiently appreciated by the layman. The analyst is frequently requested to find out the detailed composition of a complex mixture of ill-defined organic substances by "analysing" it, as though there were a standard routine method available by which all the components of any material could be determined. One reason for this confusion of thought is to be found in the difference between inorganic and organic analysis. With sufficient skill, care, and patience it is usually possible to ascertain accurately the composition of any inorganic mixture, but the majority of substances dealt with in everyday life are mixtures of a large number of organic compounds, usually of complex and little known chemical nature. It is no disparagement of the skill and science of analytical chemists to say that accurate analysis of such mixtures is impossible. Indeed, it is remarkable with what skill chemists have devised methods and tests to enable them to find out a very great deal of the nature of the complex materials presented to them. Nevertheless, many of these tests are to some extent empirical and depend for their utility largely on being carried out in a standard manner.

The need for standardisation of analytical processes, especially in dealing with organic substances such as foods and drugs, is vigorously set out in a recent paper by Mr. M. S. Salamon, which appears in the current issue of the *Analyst*. Examples were given during the discussion at the Society of Analysts which ensued on the reading of this paper. For instance, a sample of dried milk was investigated by different analysts, of whom two found 40·6 per cent. and 40·7 per cent. of lactose, whilst a third, using a different method from the other two, found only 38·6 per cent. The last-named method by a different process of calculation gives 40·6 per cent. of lactose, and it certainly seems desirable that the methods should be standardised sufficiently to avoid such large discrepancies in a comparatively simple estimation. Still more unsettling is the statement that the percentage of lactose given in an analytical report sometimes refers to the anhydrous substance and sometimes to the hydrate. In this case a definite convention should certainly be established. In the estimation of fats in milk and dried milk, some methods give consistently lower results than others, though in this case the difference is not usually so large as in the case of lactose. Even if a standard process for the estimation of fats be not agreed upon, it is desirable that the process used should always be stated so that it may be seen if results are strictly comparable. Different results are given by the various methods of determining phenols and aldehydes in essential oils; even in the case of inorganic materials the results may depend to some extent on the nature of the process. Imperfections such as these do not discredit chemical analysis; the limitations of analysis, however, should be borne in mind, and it should not be expected to accomplish the impossible.

TREATMENT OF PERNICIOUS ANÆMIA BY EXCAVATING THE BONE-MARROW.

THE bone-marrow, as well as the spleen, showing certain definite changes in pernicious anæmia, it is natural that the occasional successes following splenectomy for this disease should suggest the idea of removing the bone-marrow from the long bones. Recently this idea has materialised in Berlin, where Prof. Walterhöfer and Dr. Schramm have already operated on as many as 23 cases of pernicious anæmia during a period of little more than two years. Their achievements are so promising that they have already extended their indications for this operation, which was at first attempted only in those cases in which other older methods had failed. In a recent publication [1] they refer only briefly to the technique,[2] stating that at the suggestion of Prof. Bier they have substituted irrigations of the long bones for their original scraping operation, a current of fluid being passed through small holes bored in the tibiæ. It was noted with surprise that even almost moribund patients tolerated this operation well, and it was found feasible to evacuate the marrow of several long bones at a single operation. As good results were obtained in 48 per cent. of the cases which had been refractory to other treatment, it is claimed that the improvement effected could not be dismissed as a mere coincidence. Pernicious anæmia is notorious for its capriciousness, remissions often occurring unexpectedly and lasting a considerable time. But as the improvement observed in many of the 23 cases occurred directly after the operation, the authors dismiss as improbable the explanation that they were dealing with coincidences, and they believe that their procedure has already earned a noteworthy place in the treatment of pernicious anæmia. They have accordingly extended their indications for this treatment, which they sometimes vary with other treatments, such as arsenic medication and blood or serum transfusion. In support of this variation of treatment, they suggest that bone-marrow evacuation is but one of many means by which the regenerative processes in the body can be stimulated, and that varying the stimuli from time to time is all to the good. In cases coming to necropsy it was found that extensive regeneration of the evacuated bone-marrow had taken place, leucocytes and erythrocytes in all stages of their development being found in the new marrow. The regeneration of fat in the marrow was comparatively slight. Even when the disease steadily progressed, and the patient died, it was found that faultless regeneration of the marrow had taken place. The operation does not seem to be very dangerous, but of the durability of its achievements there must still be doubts.

---

[2] The technique of the operation was originally described in Archiv für klinische Chirurgie, Bd. cxviii., 1921.

THE PRESENT EPIDEMIC OF LETHARGIC ENCEPHALITIS.

The anticipations of the Ministry of Health in 1919 that epidemic encephalitis was likely in the future to manifest its activities in wider epidemic form appear to be only too truly realised. The seasonal incidence of encephalitis in England and Wales has been unduly high, the number of cases of the disease notified since the beginning of the year being 1612, compared with 1025 during the whole of 1923, 454 in 1922, 1470 in 1921, 890 in 1920, and 541 in 1919. In all other European countries, as well as in the United States of America, the first quarter of 1924 has shown improvement on the corresponding quarter of 1923. The returns for the week ending April 26th now show a decline in the number of notifications for England and Wales from 253 to 210. The fall has been marked in the chief centres of infection: Sheffield returns 26 cases as against 41 in the preceding week, Birmingham 17 as against 29, Newcastle 3 as against 7, and Bristol 8 as against 13. There have also been an appreciable number of sporadic cases in rural and outlying districts. In Liverpool and Sheffield several examples of multiple cases in households have occurred and the recognition of mild or abortive cases, characterised by transient palsies, stiffness of the neck muscles, febrile attacks, sore throats, or mild catarrhs is seen to be of importance in tracing the paths of case-to-case infection. On the whole, the clinical type of case seen in the present outbreak appears to be of a relatively mild degree of severity. In Sheffield out of 163 cases notified since March 10th, 20 deaths have occurred. In many instances the prodromal period of infection appears to be over the usual seven days. Many patients have a febrile onset often ascribed to "influenza," and a fortnight or more elapses before the definite signs of encephalitis are manifest. Whilst a proportion of cases can be classed as the original oculo-lethargic type or present the Parkinsonian phenomena seen in 1918, it is noteworthy that many of the cases show myoclonic movements and that fibrillary twitchings of the abdominal muscles are also common. Cortical affections are more frequently seen than in previous outbreaks; these are characterised by epileptiform convulsions sometimes associated with maniacal outbursts or insomnia. Catalepsy is rare in the present outbreak. Some patients make an unusually rapid recovery.

THE ATTEMPT TO ASSESS PHYSICAL FITNESS.

The results of certain investigations conducted during the war gave rise to the hope that by an appropriate treatment of measurements long familiar to physical anthropologists and physicians (measurement of body dimensions and of vital capacity) it might be possible to obtain simple and widely applicable methods of assessing physical condition. The Medical Research Council have collected then and since much data with the object of throwing light on this point, and though the whole of this material has not yet been analysed, a sufficiently large sample has given negative results. Inquiry as to whether any other less familiar system of measurements or tests might serve to found a rational and accurate mode of judging goodness or badness of physique has led to equally disappointing results. It seems now to be established on grounds of an analysis of measurements of young adult males,[1] in adult women,[2] and schoolboys,[3] of various ages and social class (Mumford and Young) that the inherent variability of vital capacity within homogeneous groups of apparently healthy persons is so great that inference from deviations above or below the normal of a particular combination of measurements will rarely be of service in the assessment of individual cases. In the most recent of the special report series issued by the Medical Research Council Dr. Lucy Cripps has applied to young women engaged in widely different occupations Group Captain Martin Flack's tests for physical efficiency in airmen. Her study has not resulted in the discovery of any simple or generally valid relationships. She is careful to point out that these negative findings do not detract from the value of these tests for the particular purpose for which they were devised and are used—that is, to ascertain fitness for flying. Certain side-issues of the inquiry are of interest. For example, the women subjected to the tests included 115 students at Bedford College, 241 students at a physical-training school, and 125 civil servants. Of the third-named group all, of the first many, and of the second none habitually wore corsets. The conclusion reached confirmed that of other modern observers, that the costal type of breathing at one time thought to be characteristic of women is due only to constriction of dress and that there is no essential difference in the mechanism of respiration in men and women. Another interesting fact is that among students at the physical-training college in three of the tests—vital capacity, breath-holding, and the fatigue tests—those students who have had a longer training show on the whole worse results than those in the earlier stages of training. The suggestion is that these girls may be overtrained in their third year. In connexion with this report the results recorded by Burgess Gordon, S. A. Levine, and A. Wilmaers in the current *Archives of Internal Medicine* on the vital capacity of a group of Marathon runners is of interest; their vital capacities varied a great deal from below to above normal and bore no important relation to the order in which they finished.

TUTOCAIN.

The German firm of Bayer, who introduced the substance "205" as a means of treating trypanosomiasis, have now produced a new local anæsthetic known as tutocain. It is a substance of the novocaine type, and a derivative of α-γ-amino-alcohol; it contains two asymmetric carbon atoms, but is nevertheless a racemic combination. It is very soluble and can be sterilised by boiling for a short period without undergoing decomposition. Its pharmacological properties have been described by Schulemann,[4] who states that tests on the eye of the rabbit show that a solution of ⅛ per cent. strength is potent enough to produce anæsthesia, while the lowest concentrations of novocaine and cocaine able to do so are 2 per cent. and 1/20 per cent. respectively. Thus tutocain would appear 16 times as powerful as novocaine and only two and a half times weaker than cocaine. Its effect is prolonged. Its toxicity, as tested on rabbits by intravenous injection, and on mice by subcutaneous injection, is twice as great as that of novocaine, and, so far as intravenous injection into the rabbit is concerned, about half that of cocaine. When applied to the human eye it produces no irritation, but has the drawback of causing some hyperæmia; this may be prevented by the addition of adrenalin. Various clinical reports of its use have now appeared[5]; all these are entirely favourable, both as regards its use for superficial as well as for infiltration anæsthesia. It has been used in operations for hernia, hydrocele, gastrostomy, colostomy, osteotomy (hallux valgus); also in major abdominal operations by Braun's method of splanchnic anæsthesia and also injected into the spinal canal. For nose and throat work, when used in conjunction with adrenalin, it is stated to be just as effective as cocaine. The price of tutocain is the same as that of novocaine; since, however, considerably less is required, it is cheaper than novocaine to use. Up to the present no clinical trials have been made in this country, so that it will be necessary to wait to know to what extent such favourable reports require qualification. Certain preliminary laboratory tests which have been carried out confirm the statement that it is considerably more active than novocaine. It is interesting that the Bayer firm are reported to have expressed the opinion that tutocain will prove the most valuable discovery they have made within the last ten years.

DISPOSAL OF THE DEAD.

For 50 years the Cremation Society has advocated the disposal of the dead by cremation, and the report which was read at the annual meeting on April 30th showed how much this practice has gained ground during the last half century. The total number of cremations in Great Britain during the last year was 1986, a decrease of 23 on the figures of 1922, but the report points out that there are many indications of growing interest not only in all parts of the Empire but throughout the world. When full statistics are available it is probable that the ratio which cremation bears to the death-rate will show a marked improvement, and the slight decrease is probably due to the abnormally low death-rate of the past year. The Society has given during the past year considerable attention to the question of death certification, which is intimately bound up with the future of cremation, as was pointed out in our columns recently.[1] Owing mainly to the efforts of the late Sir Malcolm Morris a fully representative committee was formed under the ægis of the Federation of Medical and Allied Services for the purpose of drafting a Bill amending the law of death certification. There is urgent need for a Bill which will leave no room for the certification of death on insufficient information, as can at present take place under the existing laws. The scope of the proposed Bill was outlined in The Lancet of Jan. 12th last. It is hoped that this Bill will be introduced into Parliament during the present session and, should it become law, it will do much to remove the existing anomalies which prevent cremation from being more widely adopted among the poorer members of the community who at present have no alternative to the common grave. The first crematorium in Wales has been established at Pontypridd, and the question of providing a crematorium for the West of England has again been brought into prominence. It is hoped that a crematorium may be established at Plymouth or some other convenient centre. The provision of a crematorium is also be to considered by the local authorities at Cardiff, Chiswick, Canterbury, and Richmond in Surrey. The disposal of the dead vitally concerns the health and welfare of the living in all classes of the population and is also of the greatest economical importance to the country at large.

The principal firms engaged in the production of insulin in Great Britain are reducing the retail price of insulin to 5*s.* per 100 units as from May 12th. The present retail price is 6*s.* 8*d.*, and is the result of a series of reductions which have taken place since insulin first came on the market here at 25*s.* per 100 units early in 1923.

The Manager of The Lancet would like to purchase copies of the issue of Feb. 2nd, 1924, for which subscribers may have no further use. He will be pleased to pay 1*s.* each for them. Such copies should be addressed to him at 423, Strand, London, W.C. 2.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LXX.—INFECTIONS OF THE HAND.

The great prevalence of hand injuries and the need of obtaining complete restoration of function for wage-earners makes their treatment of great economic importance. The following processes will be dealt with here: (1) Acute lymphangitis; (2) infections of the terminal segment of the fingers; (3) acute tenosynovitis; and (4) the infections of the fascial spaces in the palm. The degree of disability and the time lost from work depend largely upon the early and exact recognition of the type and the site of the infection. Most really bad septic hands are due to faulty diagnosis.

Prophylactic Treatment.—In all industrial works facilities for immediate treatment of minor injuries should be provided. In small works the foreman should be given instruction in elementary first-aid and be put in charge of a small surgical box, while in large concerns a special first-aid dispensary should be established. In the treatment of small cuts, pricks, and skin abrasions no attempt is made to cleanse the wound, which should be liberally painted with tincture of iodine and a dressing applied.

Acute Lymphangitis.

In this condition diagnosis is of the utmost importance, for if it is unrecognised and the finger incised, the general condition of the patient may be seriously imperilled. The finger, following a slight prick some hours previously, becomes slightly swollen with a dull ache, this condition being ushered in by a feeling of malaise or, in bad cases, by severe chill. Within a few hours the tell-tale red line has appeared in the forearm and there may be quite obvious swelling of the dorsum of the hand, though the primary site of infection remains but slightly swollen. The degree of systemic involvement varies very considerably in different cases. Treatment will be directed to the local lesion and to the general condition of the patient. Locally, oft-repeated, large hot dressings will be applied to the whole hand and forearm, while Bier's passive hyperæmia obtained by a Martin's bandage placed round the arm will be found of great service. Generally, the patient must be treated in bed, eliminative measures, such as saline purges and diuretics, must be instituted, and the patient's general condition supported by stimulants. An incision will be required only if a localised abscess develops at the site of infection or in the lymph glands at elbow or axilla. Complete recovery is often rapid, though in a few fulminating cases death cannot be avoided.

Infection of the Terminal Segment of the Fingers.

In these cases, usually, but not always, preceded by a slight prick, a stabbing pain is felt which soon gives place to a severe throbbing pain, sufficient to keep the patient awake. The end of the finger becomes swollen, red, tense, and very tender over the site of infection. The pain, swelling, and tenderness increase, and the swelling will spread down the finger and on to the dorsum of the hand, but the pain and tenderness remain localised to the terminal segment. Treatment consists of an incision on the lateral surface of the finger—never in the middle line—from the distal flexion crease to within half an inch of the tip. This will suffice in early cases, but in severe ones a second lateral incision should be made on the other side and these two joined up over the end of the finger, keeping within a quarter of an inch of the edge of the nail. The flap thus formed should be dissected up so as to open completely the fibro-fatty pocket and a slip of rubber tissue inserted between the flap and the periosteum. This promotes excellent drainage, rapid subsidence of the infection, and complete restoration of function.

---

[1] The Lancet, Feb. 16th, p. 344.

Acute Tenosynovitis.

This serious condition may be caused by a crushing accident or by infection carried from a mere scratch or prick. It will be diagnosed by severe pain; by a symmetrical enlargement of the whole finger, with the swelling spreading to the basis of the neighbouring fingers, to the palm, and particularly to the dorsum of the hand; by exquisite tenderness along the whole length of the sheath; by severe pain on passive extension of the finger, especially when the full limit of extension is reached; and by the fingers being held in the semi-flexed position, the affected finger rigidly so. This clinical picture combined with a raised temperature and pulse-rate and general malaise is unmistakable.

The infected sheath must be opened and drained, and only two problems need any discussion—viz., the site and the length of the incisions. The following procedure is based upon A. B. Kanavel's well-known work and has given admirable results. First, an incision is made either in the proximal or in the middle segment of the finger, depending on the site of the original infection. It is placed at the lateral aspect and extends the whole length of the phalanx. The tendon sheath is now laid open, but the part over the joints is left uncut so as to prevent prolapse of the tendon. By manipulation some idea can be obtained of the degree of infection in the unexposed part of the sheath, and if much pus can be squeezed out, then a second incision is made over the previously uncut segment of the finger and the sheath opened there. If the sheath contained very much pus, if the synovial surfaces are severely damaged, or if the swelling of the finger is so great as to obstruct drainage, then the two previous incisions should be joined up and the sheath opened throughout its entire length.

In dealing with the little finger, the extension of the infection into the ulna synovial bursa in the palm is to be suspected, as the sheath and the bursa are usually continuous. The recognition of this extension is by no means easy, but these points will be of use. No marked local swelling of the palm or fluctuation in the palm will occur because of the dense palmar fascia and because the infection breaks through into other structures before these signs are present. One sign is of diagnostic importance—viz., the spread of the area of exquisite tenderness from the little finger sheath to that part of the palm corresponding to the limits of the bursa. The problem is usually not so difficult as it appears, because when the sheath of the little finger has been opened, pressure over the bursa in the palm will cause pus or turbid serum to well up in the wound if the bursa be infected. In this case a grooved director should be passed through the finger incision down the sheath into the bursa. The incision is then made from the distal flexion of the palm to the level of the hook of the unciform; in order to avoid injury to the tendons and to obtain the best drainage the incision should be placed at the ulna border of the bursa.

Similarly, the radial bursa is suspect in infections of the thumb. Early diagnosis is of paramount importance in the thumb because a very large proportion give rise to secondary infection of the ulna bursa as well, thus producing a very grave condition. The signs are similar to those in finger and ulna bursal infections, the line of exquisite tenderness being the most important feature. The sheath is opened by an incision in the mid-line of the flexor surface of the thumb opposite the proximal phalanx. It is then continued in a gradual curve over the prominence of the thenar mass, ending half an inch distal to the lower margin of the anterior annular ligament. The sheath is reached by separating the two heads of the flexor brevis pollicis.

Infection of the Fascial Spaces of the Palm.

The middle palmar space lying immediately in front of the metacarpal bones of the middle, ring, and little fingers and the corresponding interossei muscles, and immediately behind the tendons in the palm, is subject to secondary infection from these three fingers, from their tendon sheaths, from the ulna bursa, and from the three lumbrical canals, as well as by direct trauma. Infection of this space is characterised by such swelling that the normal concavity of the palm is obliterated, and by tenderness over the surface area of the space. An abscess in this position may be drained on either side of the ring finger, and the guide to it is the corresponding lumbrical muscle. The decision rests with the site of the original infection, or the situation in which the pus is obviously coming to the surface; where there is any doubt the lumbrical canal between the middle and ring finger is chosen as giving the best drainage. The incision starts in the web between these two fingers and ends half-way between the distal and middle flexion creases of the palm. This opens the canal, and a pair of sinus forceps following the muscle and passed beneath the tendons will open the space, drainage being ensured by a strip of rubber tissue.

The thenar space lying on the anterior surface of the adductor transversus pollicis muscle, therefore, lies to the radial side of the middle metacarpal. Its infection may be recognised by the great swelling and tenderness of the thenar eminence. The space is opened by an incision in the dorsum of the hand along the radial side of the index metacarpal corresponding to the shaft in length. The lower border of the adductor transversus can readily be identified, and sinus forceps being passed along the palmar surface of the muscle the space is drained.

I would emphasise that in both these conditions, as indeed in every septic finger and hand, the swelling of the dorsum of the hand is most noticeable.

Operative Technique.—After-treatment.

(1) Incisions should be made under general anæsthesia; nitrous oxide alone is not suitable. (2) A tourniquet should always be used—preferably the arm compressor of a sphygmomanometer. (3) Drainage may best be obtained by rubber tissue wicks or paraffin flavine gauze—tubes should never be used. (4) No incision should be made until the surgeon has made up his mind exactly where the pus is, and exactly at what anatomical structure he is aiming. (5) No incision should ever be made upon the dorsum of the hand till every other possible site of pus elsewhere in the hand has been eliminated. Swelling of the dorsum is present in every septic hand, and incisions here do no good, only harm. (6) At the end of the operation it is often very useful to release the pressure in the arm compressor until passive congestion is obtained. This may be kept up for three hours.

All these conditions are best treated by hot boric fomentations for 48 hours, after which time small flavine dressings to the wound and light dry dressings should be used. In very bad cases baths of iodine (one drachm of the tincture to a pint of water) at 110° F. will be found soothing to the patient and useful in clearing up the worst of the infection. They should be used twice a day for 20 minutes at a time. I am of opinion that two further measures are of superlative importance: (1) To bake the hand in hot, dry air with radiant heat twice a day from the time dry dressings are being employed. Messrs. Weiss have designed a special box for me for radiant heat treatment of these hands. (2) Most important of all, after adequate drainage, is the institution of active movements at the earliest opportunity. The principle is the same as that introduced by Willems in the treatment of acute infective arthritis. Patients should be encouraged to move their fingers as early as the third day, and it will be found that they will do this at first most confidently while the hand is in the radiant heat bath. For this reason dressings should be as light as possible. If movements are encouraged as one of the recreations of convalescence no stiff fingers will result, and secondary operations, the use of typewriters, pianos, and various ingenious devices will not be needed.

R. M. HANDFIELD-JONES, F.R.C.S. Eng., M.S. Lond.,
Assistant Director of the Surgical Unit, St. Mary's Hospital.

Special Articles.

ANNUAL CONGRESS OF THE OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

THURSDAY, MAY 1ST.

THE opening meeting of the Congress took place on May 1st at the University, Glasgow, Dr. R. Maitland Ramsay, the President, in the chair. After Principal Sir Donald MacAlister had welcomed the Society to Glasgow and the University, a discussion took place on the

Physiology and Pathology of the Pupil Reactions.

Sir John Parsons dealt with the anatomy and physiology of the pupillary mechanism. He referred to the work of Anderson and Lange, and stated some essential points in the embryological and comparative anatomy of the region. He dealt with the factors upon which the pupillary reaction to light depended. He pointed out that recent work goes to prove the theories that the constrictor centre is situated near the anterior and inner end of the third nerve nucleus, that the centre for convergence is on the inner aspect about the middle, and that the accommodative fibres are centred at the posterior end of the nucleus. The superior colliculus in man has developed proprioceptive functions and fibres connect it with the vestibule. It may have connexion with the pupillary reactions. The dilator centre was believed to be near the third nerve nucleus, but recent research places it higher up, and some believe that it is behind the optic radiation and lateral to the infundibulum. The mechanism of the pupil is exceedingly complicated, it is in a constant state of unstable equilibrium, and the whole problem presents many difficulties.

Dr. Edwin Bramwell approached the subject from the physician's standpoint. The physician is concerned with eye symptoms in relation to general disease, the ophthalmologist with eye symptoms in relation to local disease. The eye symptoms in general medicine have more relation to the anatomical situation of the lesion than to its actual pathology. The physician seeks the diagnostic value of symptoms and does so in two ways, first by co-relating clinical signs with pathological findings, and secondly, by analytical study of the sign and its associated phenomena. He must never forget that an eye symptom may be present as a local manifestation, and must beware of associating it with a general disease; also a symptom may be present which is common to two conditions—e.g., a man may have myosis and an intrathoracic aneurysm, but the myosis may be due to locomotor ataxia. Argyll Robertson's famous paper was published in 1869. The sign described first by him has been reported in cases of disseminated sclerosis, encephalitis lethargica, also following trauma to the head or eyes.

Mr. R. Affleck Greeves drew attention to the alterations in the size of the pupil in relation to age. The infantile pupil is small, the adolescent large, and thereafter the pupil gradually gets smaller as the individual gets older. The small pupil of old age is due, he believes, to a stiffening of the iris and particularly of the blood-vessels. He quoted statistics showing that 4 to 10 per cent. of perfectly healthy people have unequal pupils. Enlargement of the pupil is present in many conditions. In glaucoma simplex the pupil is unaffected, in long-standing cases it is dilated, and he emphasised especially the oval pupil which is found in subacute cases and which he regards as being diagnostic. A small pupil is got in trauma when a penetrating wound is present which allows the intra-ocular tension to fall. In diabetes œdema of the pigment layer occurs which accounts for the sluggishness of the reflexes in that disease. Flattening of the pupil occurs in traumatic iridodialysis and is also an important sign of intra-ocular tumours, especially malignant ones. He quoted some very interesting illustrative cases, particularly one of a girl in whom the left pupil went through a rhythmical cycle of dilation and contraction combined with drooping of the upper lid.

In the subsequent discussion Mr. E. Treacher Collins gave a short account of some of his work on the iris, which he illustrated with numerous slides; amongst others, he demonstrated the complete absence of sphincter fibres in congenital myosis. He pointed out the curious developmental relation of the iridic and ciliary muscles, the former being epiblastic, the latter mesoblastic in origin. In certain lower animals the mechanism of pupillary reaction is entirely local; in the higher ones it is a complicated reflex process. Mr. Inglis Pollock showed a number of slides illustrating the presence of supplementary ciliary ganglia in cats and dogs. He gave an account of his work in excising the ciliary ganglia of rabbits and the subsequent action of drugs such as pilocarpine, pituitrin, and adrenalin on the pupil reaction. Mr. R. Foster Moore contributed an account of several cases of what he called non-luetic Argyll Robertson pupil. In four of them the condition was unilateral. The essential features were normal fundi, reaction to light lost, very slow contraction and relaxation on convergence, full dilation with mydriatics, presence of the knee-jerks, no history or evidence of syphilis, and completely negative physical examination. Mr. Leslie Paton pointed out that the spirochætes lay dormant in interstitial tissue and that in locomotor ataxia they were found lying in a fold at the exit of the posterior roots from which they attack the parenchymatous tissue. He suggested that a possible origin near the area involved in an Argyll Robertson pupil was to be found in a little pocket of interstitial tissue situated behind the pineal body.

In the afternoon Prof. Graham Kerr read a paper on

An Experiment in Binocular Vision.

There are, he said, three advantages of having two eyes; firstly, the individual has a spare one in case of accident; secondly, he has the advantage of binocular vision; and thirdly, he obtains an increased intensity of mental impression. It was to convince himself of the truth of the third point that he designed the experiment. He made a white figure on a black background. The figure he chose was the shape of a four-leaf clover and was about four inches in size. He held this figure about 18 inches from his eyes and by focusing upon a point beyond that distance he produced two images. By bringing his point of focus nearer he could make the two images come closer together and ultimately to overlap. He found when two leaves completely overlapped that he obtained a relatively more intense image. All attempts to measure this intensity failed owing to the unknown psychical factors involved. In his opinion the experiment showed that there is a summation of the images seen by both eyes, similar to that which occurs in animals possessing dozens and even hundreds of eyes, such as slugs, winkles, and sea-urchins. It is difficult to believe that these animals get hundreds of separate impressions of the same object if there is no summation of the images.

Sir Arnold Lawson reported a case of

Bilateral Symmetrical Detachment of the Retina with Normal Vision.

The patient was a woman of 45 who, in 1915, had a severe fall with injuries to her back and head; she was laid up for a short time, but recovered completely. She was given glasses for presbyopia in 1918 and again in 1922. In February, 1923, she complained of shadows over the right nasal field, and ophthalmoscopic examination showed a detachment of the retina on the outer side of the right eye. The rest of the fundus was normal. She was ordered to bed, and on examination a similar but less extensive detachment was found in the left eye; both eyes with presbyopic correction had normal vision. Thorough medical, radiological, and rhinological examination showed no abnormality. Since coming under observation she has had faint turns on several occasions; during these attacks she felt dizzy and fell down two or three times. They were put down by a neurologist to the occurrence of the menopause. They have not altered her retinal condition, which is exactly the same just now as when first detected in February, 1923. Mr. Hepburn suggested that the condition might be due to hæmorrhage.

Prof. Snellen (Utrecht) spoke on

Diplopia and Strabismus.

His remarks were concerned chiefly with concomitant convergent strabismus. He thought that all would agree with him in saying that the present operative treatment of squint was unsatisfactory, that advancement and tenotomy, although successful in a certain proportion of cases, frequently left the patient no better. He is of opinion that the true ætiology of the condition is not realised. In his opinion it is due to paresis of both external recti. This theory is a simple one to understand by those who believe it, but a difficult one to make unbelievers understand. Another problem is the absence of diplopia in concomitant convergent strabismus. Prof. Snellen pointed out that each eye is a complete visual entity. The eyes may be used separately for two different purposes—e.g., one eye may be looking down a microscope, and the individual's attention is concentrated on the work of that eye, but at the same time he can receive impressions of a totally different nature from the other eye, such as sudden movements in the room where he is. In strabismus the patient must fix with one or other eye, and it is obvious that he will use the better of the two; he may use one for distance and one for close work. If both eyes are equal he may use the right eye when looking to the left and the left eye when looking to the right, thus producing "alternating squint." In paralytic squint the patient attempts to use both eyes at once, and consequently he sees double.

Mr. A. F. MacCallam spoke of his

Twenty Years' Ophthalmic Work in Egypt.

He described the condition in Egypt in 1903, when he first went out, the difficulties which had to be overcome before an efficient ophthalmic service could be instituted, and how both officials and population were suspicious of the efforts which were made. The service has now got 14 hospitals as well as numerous travelling hospitals. They are staffed by Egyptians and are maintained partly by Government grants and partly by the local county councils.

Mr. Leslie Paton reported some

Ocular Complications of Spontaneous Subarachnoid Hæmorrhage.

He based his remarks upon two clinical cases and upon a review of the literature. The anterior portion of the circle of Willis is by far the most common site of hæmorrhage owing to the lack of surrounding tissue support, the poorly developed adventitia of the vessel, and the great frequency of congenital abnormality in them. Local syphilis and tubercle are not common causes; the most common causes are aneurysm, which may develop from a congenital abnormality, infective emboli, and high blood pressure. An unruptured aneurysm rarely causes eye symptoms, although certain cases of ophthalmoplegic migraine have been attributed to this. Papillœdema may follow rupture of an aneurysm immediately if there is any blocking of the optic foramen, in a few days if the intracranial pressure increases slowly, and it may not appear for some months if a cystic hæmatoma is formed. Hæmorrhage appearing in the fundi is due to leakage along the nerve sheath and through the lamina cribrosa.

Dr. Brownlow Riddell read a paper upon

Eye Symptoms in the Early Diagnosis of Disseminated Sclerosis.

He based his remarks upon a series of cases which had come under his observation since 1897. He had been very much impressed by the frequency in which a retrobulbar neuritis or a transient attack of diplopia preceded any other gross evidence of organic change. In a number of such cases—i.e., retrobulbar neuritis or transient diplopia—careful physical examination revealed unsuspected evidence of the disease, and in recent years serological examination has helped to confirm the diagnosis. He urged that all such cases at an eye clinic should be looked upon with suspicion, although he was well aware that the immediate ophthalmological prognosis was good. A lively discussion followed this paper, during which Dr. de Schweinitz expressed the opinion that even after the accessory sinuses had been operated upon in cases of retrobulbar neuritis in which they were believed to be the cause, disseminated sclerosis could not be eliminated, and he entirely agreed with the essayist upon the points which he emphasised. Mr. T. Harrison Butler pointed out the difficulty in the differential diagnosis of disseminated sclerosis and of certain mild cases of encephalitis lethargica. Messrs. Leslie Paton, Basil Graves, Gray Clegg, A. J. Ballantyne, Johnson Taylor, H. L. G. Leask, and Bernard Cridland also spoke.

Friday, May 2nd.

On May 2nd the general business meeting was held and the report of the Council of British Ophthalmologists was received. Mr. E. Treacher Collins was elected President for the session 1924–25. In the afternoon a reception was held at the University by Sir Donald and Lady MacAlister.

Clinical Meeting.

In the forenoon a successful clinical meeting was held at the Glasgow Eye Infirmary. Cases of great interest and diversity were demonstrated by the local members of the Society; and Mr. Harrison Butler, with the assistance of Mr. Basil Graves, Dr. W. C. Souter, and Mr. A. H. H. Sinclair, helped to initiate some of the members in the use of the Gullstrand slit lamp and corneal microscope. Mr. Butler gave also a demonstration of the use of Hess's apparatus for the investigation of muscle paresis. This gave rise to some interesting discussion, but as most of those present were unfamiliar with its use, its value could not be finally assessed. It seemed, however, to be a method which is admirably adapted for use in very young or very unintelligent patients, but a little elaborate for routine dispensary work.

Dr. J. Rowan demonstrated some of the cases of congenital cataract upon which he had operated in the manner described in his paper, which he read to the Society later. Dr. Wright Thomson showed some cases of glaucoma upon which he had performed Bentzen's modification of Elliot's operation, where an inferior incision is made close to the corneo-scleral margin and the conjunctiva allowed to retract slightly. This permits of clearer access for the trephine and reduces the danger of "button holing." Dr. Ballantyne showed two cases of birth injury to the cornea, one of unilateral congenital anophthalmos and a most interesting case of a rare form of muscular dystrophy. This case showed involvement of the extra-ocular muscles and the muscles of the face on both sides. Dr. Riddell and Dr. Hislop Manson demonstrated three members of a family of "blue sclerotics." Fourteen members of the family have been traced and the condition is present in varying degrees in nine of them. The family includes two girls, twins, one with and the other without the condition. The affected members have had more than a fair share of fractures, but there is no history of deafness nor of hæmophilia. Dr. Riddell showed a case of choroideremia with a family history of retinitis pigmentosa. Mr. Inglis Pollock had numerous cases showing the results of operation on glaucoma by the Lagrange method and of simple extraction followed by early division.

The Gullstrand Slit Lamp and Corneal Microscope.

This demonstration was of the greatest interest, and a practical demonstration of the instruments is almost essential before one can grasp the rudiments of the subject or realise the fields of research which their use open up. As an illustration, the arrangement of the instruments can be compared to two knives plunged into the centre of an apple at different angles but on the same horizontal plane. One knife represents the slit lamp beam, the other the axis of the corneal microscope through which the observer looks, and the apple represents the eye. Only that portion of the eye traversed by the beam is illuminated directly, and obviously that is the only portion which is seen when the observer looks through the corneal microscope. There are numerous adjustments which can be carried out, the size and shape of the slit lamp beam can be altered, and the angle of approach both of the microscope and the lamp can be varied to suit the object of the observer. It is clear that numerous corrections must be made for the different refractive indices of the strata through which the beam passes and for other sources of error, such as reflection of the beam from the various reflecting surfaces which it strikes, and for an impression of intensification of the beam where light is thrown back towards the observer as it passes into a tissue which has a different refractive index. These factors have all to be taken into account when translating what one thinks one sees into what is actually present. Mr. Butler, by means of a few simple diagrams, made it easy for inexpert members of the Congress to understand what they saw in the normal eye. He also demonstrated the slit lamp features of certain pathological conditions, such as iritis, cataract, corneal opacities, &c. The solution of many problems may be hastened by its use—for example, that of developmental errors. One of its great practical uses is that sympathetic ophthalmia may be detected at a very much earlier stage than formerly—before, in fact, the clinical picture of the disease has had time to develop.

At the evening session held at the University, Mr. Butler followed up his work of the morning with a paper on the

Anatomy of the Normal Lens as Revealed by the Slit Lamp.

He explained his own difficulties in approaching the subject. Most of the literature was in German, a great deal of it was diffuse and obscure, and there was at present no text-book on the subject. Another problem to be faced was that, having read the literature, he found the application of it extremely difficult, as each observer had his own ideas about the interpretation of what he saw and his own standards in the differentiation of light, shade, and colours. The preparation of illustrations was made difficult owing to circumstances which forced them to be only memory pictures. The final problem was that, having mastered the technique and the literature, it was found that no two lenses appeared alike, and consequently the difficulty of explaining what a normal lens should look like was very greatly increased. This could only be solved by each observer examining clinically normal eyes and forming his own opinion as to what was and what was not early pathological change. For example, in the morning he had demonstrated pigment granules to be present on the anterior lens capsule of the eye of one of the members of the Congress. This was of no significance. Small areas of what appeared to be cataractous change were seen so frequently in individuals of all ages who were perfectly well that they were of no significance, so far as our present knowledge went.

Mr. Butler exhibited an instructive series of drawings prepared by himself showing the normal lens in many of its normal variations; he also demonstrated certain fallacies which have to be avoided. The anterior Y and posterior inverted Y could usually be seen; as was well known, these were the results of the suturing of the lens. Numerous other sutures could also be appreciated in healthy people; the lens nuclei could be shown and the various layers which went to make up the lens appeared with a variety of colour and shade quite unsuspected before the introduction of this aid to clinical investigation. A small opacity of no pathological significance in the anterior portion of the lens might throw an intense shadow across the field of vision and might lead the observer into the error of supposing that it was due to a more important change. The literature was already showing signs of inaccurate nomenclature, and he suggested some simpler terms which could be used to replace those resulting from literal translation from the German.

Later in the evening Mr. Basil Graves gave a paper on the

Histological and Slit Lamp Features of a Limbus Tumour.

Owing to the short time at his disposal his demonstration had to be hurried. He explained certain difficulties, particularly of an optical nature, which he had found in the use of the slit lamp, and demonstrated their solution by means of simple diagrams. He also drew attention to the occurrence of a copper bronze reflection from normal epithelium on the posterior corneal surface when the angle of incidence of the slit lamp beam and of the axis of the observer's eye were exactly the same. The object of his paper was to correlate the ordinary clinical, histological, and pathological features with the slit lamp findings in the case of a boy who had a small limbus tumour. Examination by the slit lamp demonstrated its pigmented character and also a thickening of the connective tissue immediately behind it. It was removed and found histologically to be a tumour somewhat similar to a skin mole or innocent melanoma.

Mr. J. Gray Clegg read a paper on

Central Scotoma in Anterior Uveitis.

Several cases of this nature had come under his observation, and he was of opinion that the association would be found, if looked for, in a proportion of cases of anterior uveitis. In most of his cases the condition cleared up with the subsidence of the primary disease. He expressed the opinion that the condition was analogous to the toxic scotomata caused by alcohol, tobacco, T.N.T., &c., except that in the cases he was reporting the toxic effect was produced by direct spread through the vitreous humour. He described a few of his cases in detail, and urged members of the Society to investigate cases of iridocyclitis for the presence of scotoma.

Dr. Ivy McKenzie spoke on the

Trigeminal Nerve as an Integrating Mechanism between the Nose and Eyes.

He remarked on the complexity of the fifth nerve and its connexions, and expressed the opinion that it was one of the most complicated nerves in the body. His remarks turned on his belief in the theory that sensory nerves can carry stimuli from the central nervous system to the periphery. He regarded the existence of antidromic impulses as proved beyond doubt. He applied this theory to the explanation of certain forms of headache; the fifth nerve nucleus was irritated by some poison or toxin and the impulses carried out from it were referred to the head and so produced headache. On similar lines he suggested an explanation of the frequent clinical association of giddiness, vertigo, vomiting, and headache, in the close association in the brain of the nuclei and centres connected with these symptoms. He suggested that a parallel state of affairs existed with regard to the ulnar nerve; symptoms might be referred to the area supplied by it in conditions such as pleurisy, angina pectoris, and gall-stones. This was owing to the fact that stimuli from the diseased region were referred to the central nervous system and arrived, in the diseases chosen for illustration, about the position where the sympathetic endings in the cord could irritate the nuclei from which the ulnar nerve fibres arose. Further, the fifth nerve nucleus was connected up within itself by a network of "fibræ comitantes," which could be used, along with the antidromic theory, to explain numerous conditions such as the stimuli from a diseased tooth being referred to a sound one or to the supra-orbital region. These he described as examples of "irradiation of stimuli." He suggested the application of these theories to eye conditions, particularly trophic and nutritional disturbances, such as herpes and certain forms of ocular pain.

Sir John Parsons did not agree with the statement that the antidromic theory was generally accepted. He had an idea (which he found a little difficult to express clearly) that the "epicritic" distribution of headache was untrue. To his mind certain headaches were much more like a "protopathic" explosion, a primitive nerve action, and the distribution could not be mapped out according to the branches of the fifth nerve.

Mr. Leslie Paton referred to Head's brilliant researches, and also doubted the antidromic theory. He thought that many of the illustrations used to back it up could be explained by the presence of a virus possessing neurotropic and dermotropic characters, and quoted experimental work on rabbits in which herpes had been produced by the dermotropic action of a virus. By transferring the infection through a series of rabbits the neurotropic elements became exalted and symptoms of encephalitis lethargica were produced. In his opinion, all antidromic phenomena could be explained by assuming that the neurotropic and dermotropic powers of the virus manifested themselves at the same time.

Miss Ida C. Mann read a paper on

Coloboma Iridis and its Embryology.

She mentioned several theories which had been put forward as explanations, but for simplicity did not go into the details of their rejection. Any theory which was to explain the condition must be capable of application to all the positions in which coloboma iridis occurs; to the fact that the fissure was sometimes incomplete; to partial colobomata which appeared like holes in the iris; and also to aniridia, a condition the existence of which the speaker appeared to doubt. In a beautiful series of drawings she illustrated what she believed to be the true developmental reasons. Certain branches of the hyaloid artery which break up to form the vascular capsule of the lens pass out of the extreme pupillary end of the cleft to anastomose with vessels outside the developing optic cup. These anastomosing vessels were most marked at the sites where coloboma iridis was most common—i.e., downwards and on the inner and outer sides. If any one of these vessels and its surrounding tissue persisted in a well-developed state, the advancing border of the optic cup, which in course of time would form the retinal iris, was arrested and the unobstructed portion on each side swept forward, thus forming a cleft in what would otherwise be a normal iris. Pathological evidence of the truth of this theory was found on examination of the developing eye of an anencephalic embryo.

Prof. T. H. Bryce said that he was extremely interested in the paper and thought that the explanation put forward was very reasonable. Mr. E. Treacher Collins also spoke.

SATURDAY, MAY 3RD.

On the morning of May 3rd the final meeting of the Congress was held at the University. Dr. John Marshall gave an account of a case of

Persistent Hyaloid Artery and Tunica Vasculosa, with Buphthalmos.

The patient was a child of 3 who had been seen when about a year old; the condition was diagnosed as pseudo-glioma. When seen later she was suffering from buphthalmos with iris bombé and intercalary staphyloma. The eye was removed on account of its size (by Dr. Riddell). He described the pathological findings and asked for information as to the possibility of operative treatment along the lines of a trephining operation in the early stage, thus preventing stretching of the globe. Mr. E. Treacher Collins and Sir John Parsons gave their views on the condition.

Dr. John Rowan reported the results of

Iridectomy in Congenital Cataract.

Among the points which he advanced were: (1) The patient did not require to wear glasses; (2) the condition, as a general rule, was not progressive; and (3) it was to be preferred to more radical methods of cure. He performed his iridectomy downwards and made it as small as possible. On the previous day he had been able to demonstrate cases which had been operated upon over 20 years ago. He gave a short account of some of his more recent cases as evidence in support of this method of treatment. An interesting discussion followed, in which Dr. A. J. Ballantyne, Dr. W. G. Sym, Sir Arnold Lawson, Mr. J. F. Cunningham, Mr. Johnson Taylor, Mr. Gray Clegg, Mr. Herbert Fisher, Sir John Parsons, Mr. Treacher Collins, and Dr. James A. Wilson took part.

Dr. G. F. Alexander read two communications: one describing an operation in failure of iridectomy for glaucoma, and the other on the advantages of a strong solution of atropine in removal of cataract. The points raised by the speaker were essentially concerned with technique.

Dr. S. Spence Meighan reported two cases of

Traumatic Vesicular Keratitis.

He said that this was a rare condition. De Schweinitz had seen three cases in 12,000 patients. He pointed out its extreme resistance to all forms of treatment and the difficulty of diagnosis in the first instance. One of his cases was present at the clinical meeting on the previous day. There was a good deal of discussion following his remarks, in which, amongst others, the following spoke: Dr. Ballantyne, Mr. Johnson Taylor, Dr. Wilson, Sir Arnold Lawson, and Mr. Paton. The last named made the most interesting suggestion that the resistance to treatment and anæsthesia of the cornea present in this condition might be due to failure on the part of the minute nerve endings in the cornea to regenerate, thus producing in the cornea a condition analogous to "stump neuromas."

Mr. Inglis Pollock urged the advantage of early division after simple extraction operations. This second operation he carried out, if all went well, on the fifteenth day after the primary one. He advocated the use of a Ziegler knife in preference to a needle.

Conclusion of the Meeting.

The President, at the conclusion of the meeting, expressed the pleasure and honour that it had been to him to welcome the Society to the place where MacKenzie had lived and worked. His name would always be a source of inspiration to ophthalmologists. Mr. Herbert Fisher expressed for the visiting members of the Society their gratitude and appreciation of all that had been done to make the Congress the great success it had been. He desired the meeting to instruct the Secretary to express their special gratitude to the Principal of the University, Prof. Graham Kerr, and the other members of the staff who had done so much for them by placing the Department of Zoology at their disposal.

SCIENTIFIC MUSEUM.

In connexion with the Congress a museum was arranged, and the following were among the most interesting exhibits. Dr. A. Maitland Ramsay and Dr. Alex. Garrow showed a beautiful series of autochrome plates of diseases of the eye. Dr. Leslie Buchanan showed original papers of great historical interest, such as a first edition of Helmholtz's paper on the ophthalmoscope, some of MacKenzie's instruments, and his paper on the treatment of strabismus. Dr. Ballantyne displayed a series of fundus drawings executed by himself. Prof. Bryce showed specimens illustrative of the development and anatomy of the eye, from the Department of Anatomy. Prof. Graham Kerr showed microscopic preparations illustrative of the comparative anatomy of the eye, from the Department of Zoology, and a demonstration of the use of the binocular eye-piece with high power microscopic objectives.

Exhibits of Value in the Teaching of Ophthalmology.

The scientific museum in connexion with the Congress gave evidence of the admirable teaching facilities offered by the various departments represented. Among notable exhibits were Cleland's famous series of dissections of the eye in various classes of vertebrates, which make one wonder whether we are not losing the art of dissection. Which of us would feel quite confident if asked to display intact the membrane of Descemet with scalpel and forceps?

Another interesting section showed a series of models (illustrating phases of development in vertebrates), which had been made by the students in the class of embryology themselves. With this exhibit was associated a series of most perfect sections of the embryonic eye in lepidosiren.

The most striking exhibit, perhaps, from the teaching point of view, was a large series of autochrome plates of external diseases of the eye. These were shown by Dr. Maitland Ramsay, Dr. John Rowan, and Dr. Alex. Garrow. Dr. Rowan's series were stereoscopic and of extreme value to the student of eye diseases, as one almost seemed to be looking at the actual patient. The colouring was perfect. In most cases the picture showed the head and shoulders of the patient, so that an excellent idea of the general type of person could be formed, obviously of much more value than a picture of an isolated eye, however well drawn or photographed. The plates illustrating interstitial keratitis, marginal blepharitis, rodent ulcer of the lids, and ophthalmia neonatorum were specially valuable in this respect. Everyone knows that systematic teaching in the out-patient department is sometimes marred by the failure of a sufficiently great variety of cases, and a series of such plates, particularly stereoscopic, would be a most useful adjunct, allowing of comparison of a whole series of similar conditions with the patient of the moment.

At this exhibition one was reminded strongly of the dictum that while the older universities supply tradition and the stimulus to research, it is to the northern universities that one must go to see teaching institutions par excellence. In the south the undergraduate may sometimes be looked on as a necessary encumbrance; in the north he is the central figure in the university and his every requirement is catered for.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Medical Officer and the Medical Inspector.

VERY many private enterprises and business houses make themselves responsible for the medical care of their employees, victims of industrial accidents or diseases, while those suffering from injuries received in the war obtain medical assistance under legal regulations. It is now suggested by the legislature to subject a third of the French population to compulsory insurance against sickness, and to give to the medical man in charge of industrial personnel the double rôle of doctor and medical inspector or controller. Dr. Balthazard, Professor of Legal Medicine in the Paris Faculty, has therefore drawn the attention of the Academy of Medicine to this proposal as one which violates the principles of the profession, for the doctor in charge in such circumstances of sick employees, if he were also the inspector for the employers, would be obliged to inform his principals of the diagnosis, cause, and probable duration of the illness. It is obvious that the provision of medical attention for the workers may provoke misunderstanding between the employers and the workmen, but the doctor who actually treats the men is the only person qualified to look after the interests of the sick, and it is impossible that a doctor paid by the employers can also be constituted arbiter between them and the sick men under his care. Certain business concerns, whether private or public, like gas companies, police bureaux, or the Assistance Publique, realise the necessity for the distinction which the law has lost sight of, arranging that while the sick man is looked after by the doctor of his choice, control is exercised by another medical man nominated by the employers. While medical inspection is to be organised alike for the victims of industrial accidents and those who are drawing legal pensions, it is established by law that neither the doctor in charge nor the doctor nominated by the employers can be selected as an expert in legal proceedings consequent on industrial injury. On the motion of Prof. Balthazard the following resolution was passed by the Academy: "In the interests of the sick who ought to find in their own doctors their natural protection, and mindful also of the principles guarding medical confidence, the Academy affirms that in every organisation for medical treatment the rôle of the doctor actually treating must be considered incompatible with that of controller or inspector. In matters of expert treatment the Academy affirms that the incompatibility is yet more strict between the duties of the expert and those of either the doctor in charge or of the inspector."

The Children of Tuberculous Mothers.

It seems well established to-day that tuberculous infection of the fœtus, produced through the placenta, is of infinitely rare occurrence, and that the infection of nurslings born of tuberculous mothers is a result of familial contagion. But it is under discussion whether these children are born with a diminished coefficient of vitality, as in France Landouzy and Barbier have maintained. In contravention of this view Debré thought it possible to establish that these children are born with a weight of about 3250 g.—i.e., a weight little, if any, below the average. Quite recently Prof. Couvelaire, who has made a study of children born from tuberculous mothers, brought up by foster-parents and withdrawn from contact with their mothers, has revealed to the Society of Obstetrics and Gynæcology at Paris the very high mortality among them—viz., 38 per cent. in the first month. Most of the infants died from no demonstrable cause—one might say that they went out like lamps unsupplied with oil.

Dr. Vignes laid down at one of the last sittings of the Society of Biology that, save for a few exceptions, if one sets down the weight of the children born of tuberculous mothers at the exact term of gestation and compares this weight with the average weight observed at the same period among the newly-born in Paris, we find some instances of weights superior to the average or approaching that average, and a very great number of children who are inferior in weight, that inferiority being more accentuated among children of multiparæ than among those of primiparæ. The results of this work are in contradiction to those of another communication by the same author to the French Association for the Study of Cancer (Séance, March, 1924), for children born of cancerous mothers, even if the cancer was grave, had generally a weight fairly approaching the average.

Syphilis of the Œsophagus.

Even before the invention of radioscopy syphilis of the œsophagus was considered very rare, and now Dr. Guisez, of Paris, has reported to the Academy of Medicine on a series of more than 3000 œsophagoscopies, saying that he has only observed among them one well-established case and one doubtful case of syphilis. The œsophagus is one of the organs that is most rarely attacked by syphilitic lesions, and it would be well to take notice of this fact and to drop the perpetual inclusion of syphilis in the differential diagnosis of the causes of severe stenosis of this tube, leading to the institution and prolongation of treatment which may have ill consequences for the patients. It would seem that the majority of the cases published under the name of syphilis of the œsophagus were simple inflammatory stenosis, an affection which is recognised under œsophagoscopy to be more frequent than has previously been suspected.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following table gives some of the principal statistics of the County Borough of Reading and the Urban District of Finchley for the year 1923:—

Name of borough.	Estimated mid-year population (R.-G.).	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
			All causes.	Tuberculosis.	Cancer.	Respiratory with influenza.	Neonatal mortality.	Infant mortality.	Maternal mort. from childbirth.
Reading (C.B.)	93,160	18·3	11·1	1·2	1·2	1·6	29	52	6·4
Finchley (U.D.)	47,020	15·6	9·0	0·7	1·5	1·2	23	38	5·4

Reading.

Dr. H. J. Milligan indicates some of the changes in the age distribution of the population revealed by the census—viz., a deficiency in the numbers of children below 10 years and of males at the mid-period of life resulting from the war; and an increasing proportion of persons of advanced years, indicating an increased expectation of life, the result of improving sanitary conditions. Housing conditions, however, do not improve. Of 131 houses erected during 1923, 20 were part of a municipal scheme. The shortage of cottages continues, and many existing "unfit" houses would be closed were there alternative accommodation. The number of applicants for houses is as high as it was two years ago. The death-rate from pulmonary tuberculosis, which fell to 0·89 in 1919, has tended to remain stationary and last year showed an increase to 0·99. Extensive use is made of the 33 shelters provided by the council for open-air treatment and 26 of these were in regular use in the month of December, some in the day-time only. The number of new Reading cases of syphilis and gonorrhœa treated at the clinic during 1923 were 32 and 46 respectively, as compared with 153 and 168 in 1919, the year of maximum incidence. Dellwood Maternity Home continues its eminently successful work. During the year 285 patients were admitted. Of these, 91 came from a one-roomed home, 97 from a two-roomed, and 97 from homes of more than two rooms. Of the latter group 37 were admitted as the patients of general practitioners. Thirty-seven of the patients were admitted free of charge and the remainder paid on the average £1 6*s*. 6*d*. per week. The Home takes trained nurses as pupil-midwives and nine pupils have passed the C.M.B. examination since the training scheme was begun. A considerable proportion of the milk now sold in the borough is "Grade A (Tuberculin-tested)." Dr. Milligan also reports that, although much of the milk sold is subjected to a process of heating, no licences have been issued for the sale of "pasteurised" milk.

The school report includes a comparison of the physique of Reading and American children, much to the advantage of the latter. The methods used and the social status of the children are said to be comparable. Dr. Agnes Bernfeld reports successful results from the treatment of chronic otorrhœa by zinc ionisation. The method has been in force for over three months and 28 cases have been treated. Of these, 20 cases have been apparently cured and the remainder improved. Miss Marion S. Mackinnon succeeded Mr. W. Adderley as school dentist in May, but the increasing number of those who accepted treatment made it impossible to inspect all the schools during the year. It is suggested that the children of parents who consistently refuse treatment should be entirely disregarded and effort concentrated on the 6 to 8 year old groups and the following up of children who regularly avail themselves of treatment. Miss Mackinnon also hopes to enlist the help of the older children and encourage them to interest themselves in the oral hygiene of their younger brothers and sisters.

Finchley.

Dr. Wilson Jameson reports that the joint ownership of the Hornsey Hospital by Hornsey, Wood Green, and Finchley has proved very satisfactory. The question of providing cubicle isolation wards is now under consideration. A motor ambulance for the conveyance of persons injured by street accidents and suffering from non-infectious complaints was purchased in August for £376. From August 10th. 1923, to March 6th, 1924, the ambulance was called out 177 times. The payments received were £95 and the running costs were £56. Both the public and the general practitioners have welcomed the arrangement. The details of the census returns appear to show that Finchley since the war is no worse off as regards housing than it was before the war. This is probably accounted for by the fact that the number of the average family has declined from 4·33 to 3·93. There is, however, more herding of families in houses only intended for one family. Subletting was found in 35·7 per cent. of 646 typical working-class houses; and in the 200 houses erected under the council's assisted housing scheme subletting was discovered in 30 per cent. In Finchley three firms now produce "designated" milk. One firm produces "certified" milk and "Grade A (Tuberculin-tested)" milk; another produces "Grade A" milk; and the third "pasteurised" milk. In January, 1924, milk with no official guarantee was sold in Finchley at 8*d*. per quart, whereas "pasteurised" milk cost 8*d*., "Grade A" milk 10*d*., "Grade A (Tuberculin-tested)" 1*s*., and "certified" milk 1*s*. 2*d*. per quart. The provision of a refuse destructor is still under consideration. In the meantime the old method of burning refuse in heaps at the sewage farm still continues.

In his report as school medical officer Dr. Jameson refers to the great benefits likely to result from the decision of the Education Committee to appoint an organiser of physical training. One of the head teachers who had special qualifications for the post, Mr. G. R. Mellor, was appointed and took up his new duties in November. A good beginning has been made by a survey of the possibilities of the scheme, first, by a questionnaire addressed to all the head teachers, and secondly, by observing all the teachers responsible for physical training at work. This was followed by two introductory lectures—viz., "The School as a Centre of Preventive Medicine," designed to illustrate the comprehensiveness of the term "Physical Education," and its great value both to education and preventive medicine, and a second lecture, largely a résumé of the 1919 syllabus of physical training. The syllabus is now being taken in greater detail at weekly meetings of the teachers. The organiser is, of course, extending his interest to swimming, organised games, and all forms of physical recreation. Altogether the new departure is being taken up with enthusiasm and bids fair to be a great success. The school medical officer conducts the medical inspection of the two secondary schools on behalf of the Middlesex County Council, and has the satisfaction of recording that, mainly owing to the interest shown by the headmasters, all the cases referred for treatment in 1922, with the exception of three, obtained treatment before the end of 1923, and this in spite of the fact that there is no arrangement in force for the provision of treatment in the case of the secondary schools. The school dentist, Mr. G. H. W. Randell, reports that 80 per cent. of the children "referred" presented themselves at the clinic for treatment. He deplores the idea that the average adult still regards dentistry as a form of torture. Probably in these days of painless dentistry and the widespread recognition of the enormous benefits of early treatment, this "idea" is rather the perpetuation of an obsolete joke, which had its origin when dentistry was not what it is now. As Mr. Randell points out, the dread of dental treatment will, in course of time, disappear, and the much appreciated coöperation of the head teachers is a most valuable means to this end.

INFECTIOUS DISEASES IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 26TH, 1924.

Notifications.—The following cases of infectious disease were notified during the week—namely: Small-pox, 124; scarlet fever, 1328; diphtheria, 615; enteric fever, 53; pneumonia, 1674; puerperal fever, 51; cerebro-spinal fever, 10; acute poliomyelitis, 5; acute polioencephalitis, 1; encephalitis lethargica, 212; dysentery, 3; ophthalmia neonatorum, 117. No cases of cholera, plague, or typhus fever were notified. The cases of encephalitis lethargica, 41 fewer than in the previous week, were notified in the following counties: London, 31; Chester, 6; Derby, 9; Devon, 4; Durham, 4; Essex, 8; Gloucester, 13; Kent, 4; Lancaster, 27; Lincoln, 5; Middlesex, 4; Northumberland, 7; Nottingham, 4; Warwick, 27; Yorks W.R., 37; and elsewhere in smaller number.

Deaths.—In the aggregate of great towns, the deaths from influenza fell from 282 to 218. In London the deaths from diphtheria numbered 12, from measles 57 (same as last week), from influenza 21 (a drop of one-half).

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdrs. J. G. Peebles and L. S. Whitwam are placed on the retd. list.

J. V. Williams to be Surg. Lt.

The following appts. have been notified: Surg. Comdrs. A. F. O. Sankey to R.N. Hospital, Portland; E. L. Markham to the *Castor;* H. E. Perkins to the R.N. Hospital, Bermuda; and A. G. V. French to the *Canterbury*, temp. on commissioning.

ARMY MEDICAL SERVICE.

Col. H. P. W. Barrow, late R.A.M.C., to be Dir. of Hygiene, vice Maj.-Gen. W. W. O. Beveridge.

The undermentioned Maj.-Gens. retire on retd. pay: W. W. O. Beveridge, K.H.P., late R.A.M.C.; and E. M. Pilcher, K.H.S., late R.A.M.C.

Lt.-Col. F. Ashe, from R.A.M.C., to be Col.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. and Bt. Col. J. W. West, K.H.S., is granted the temp. rank of Col. whilst empld. as Consulting Surg. to the British Army, vice Maj.-Gen. E. M. Pilcher.

Capt. L. J. Sheil retires, receiving a gratuity.

TERRITORIAL ARMY.

Supernumerary for Service with O.T.C.—Capts. (Local Majs.) P. H. Mitchiner and G. A. Williamson to be Majs.

A. MacPherson to be Lt.

ROYAL AIR FORCE.

Flying Officer K. R. Smith relinquishes his temp. commission on ceasing to be employed.

INDIAN MEDICAL SERVICE.

Maj.-Gen. A. Hooton has been confirmed in the appointment of Surgeon-General with the Bombay Government in succession to Maj.-Gen. W. J. Jennings, K.H.S., on leave, pending retirement. Lt.-Col. W. O'S. Murphy has returned from leave and assumed the appointment of Director of Public Health with the Bombay Government. Lt.-Col. A. W. Tuke, civil surgeon, Ahmedabad, has proceeded on leave.

Dover: New Dental Clinic.—The adult dental clinic presented to Dover by Major J. J. Astor, M.P., will be opened to-day (Friday). Major Astor has undertaken to meet the expenses of the clinic for the first two years, and the staffing and other arrangements have been approved by the town council. The clinic adjoins the municipal buildings.

"Audi alteram partem."

SIR MALCOLM MORRIS MEMORIAL FUND.

To the Editor of THE LANCET.

Sir,—The death of Sir Malcolm Morris, on Feb. 19th last, marks the passing of one who was widely known and greatly respected, both by his professional colleagues and the public generally, for his work in connexion with dermatology, tuberculosis, public health, and medical literature.

To perpetuate his memory it was resolved at a recent meeting of representatives of the various hospitals and organisations with which he was particularly associated, to endeavour to raise a sum of money sufficient to provide for an annual lecture on the preventive aspects of public health and dermatology. If funds permit it is hoped also to endow a bed for cases of skin disease at St. Mary's Hospital, London. These objects are known to accord with Sir Malcolm Morris's expressed view that the only fitting memorial to a life of successful endeavour is one that carries on the causes to which that life was devoted.

A representative committee has been formed, and we invite contributions, in any amounts, which will be gratefully acknowledged if forwarded to the hon. treasurers, Malcolm Morris Memorial Fund, at 12, Stratford-place, London, W. 1.

We are, Sir, yours faithfully,

Thomas Horder,
Federation of Medical and Allied Services.
E. B. Turner,
British Medical Association.
E. Graham Little,
St. Mary's Hospital.
C. Neville Rolfe,
Nat. Council for Combating Ven. Diseases.
W. Griffith,
St. John's Hospital.
A. E. Hayward Pinch,
Radium Institute.
H. T. Herring,
Cremation Society of England.
N. Howard Mummery,
Hon. Secretary.

May 1st, 1924.

A CRITICAL EXAMINATION OF PSYCHO-ANALYSIS.

To the Editor of THE LANCET.

Sir,—In The Lancet of April 26th Dr. Wohlgemuth suggests that he has been successful in showing that psycho-analysis and its means of penetrating the unconscious is unscientific and fallacious, and that, in common with other psycho-analysts, I am avoiding the main thesis in side-tracking the discussion upon unessential details. As Dr. Wohlgemuth seems to be incapable of understanding the psycho-analytic conception of the unconscious it is difficult to know what kind of proof he requires. He has not employed the technique himself, but presumably knows that associations made by the patient are recorded in plenty and that their reactions have been described. These communications are the proof of the need for the theory. Dr. Wohlgemuth is in the position of a critic of chemical theory who refuses to handle a test-tube. I referred him to one book in which the "test-tube" results are recorded independently of theory. The point of discussion concerning abreaction is one which he raised himself; his denial of results which are confirmed by responsible English physicians is surely evidence of a desire to reject proofs when they are offered. What does he require?

I am, Sir, yours faithfully,

Robert M. Riggall.

Wimpole-street, W., May 3rd, 1924.

THE NARCOTIC ACTION OF PURE ETHER.

To the Editor of THE LANCET.

SIR,—On March 7th I had the honour of addressing the Section of Anæsthetics of the Royal Society of Medicine on the subject of the Narcotic Action of Purest Ether. A short report of this lecture appeared in THE LANCET of March 15th, 1924 (p. 561), and a full account will be published in the Proceedings of the Society.

The starting-point of our research on the narcotic action of various ethers was the statement of Mackenzie Wallis, that purest ether had no narcotic action at all, but was only rendered narcotic by the action of impurities. Of these impurities ethylene and certain ketones of the middle of the series were said to be the most important ones, and consequently a commercial product, "Ethanesal," was put on the market, which was later stated by Wallis to contain 5 per cent. of methylethylketone. Mackenzie Wallis and some others stated that this preparation had a narcotic action superior to that of ether.

In my lecture mentioned above I made the statement—which fully confirmed the former work of Dale, Hadfield, and King—that the purest ether obtainable has the same narcotic action as the ordinary ethers used, whilst also the action of "Ethanesal" did not in any way differ from the action of purest ether. I also mentioned that, as a rule, addition of various impurities to ether did not materially change the *narcotic* action of ether, but that methylethylketone made an exception, in that addition of 5 per cent. of this substance changed the action of ether. On narcotising cats with this mixture I had found that less was necessary to keep the animals in a certain depth of narcosis during an hour than in the case of pure ether. This finding seemed interesting in view of the fact that "Ethanesal" was claimed to contain methylethylketone in this proportion. It was then necessary, however, to investigate the action of mixtures of ether with 5 per cent. of methylethylketone further, paying special attention to eventual toxic actions. After returning from England these investigations were started, but reached an unexpectedly quick conclusion, since we observed that this mixture is extremely toxic. Cats narcotised with it on two consecutive days (or with one day's interruption) usually die. On making a necropsy we found hæmorrhages in lungs, liver, and kidneys, and blood and bilirubin in the urine.

I have felt obliged to make early mention of this result in this way, since in my lecture I had mentioned the *possibility* that addition of methylethylketone to ether might prove to be useful, and I feared that this statement, together with Wallis's claim that "Ethanesal" contains 5 per cent. of methylethylketone, might induce someone to try a mixture of pure ether and 5 per cent. of methylethylketone on men, which would be little short of disastrous.

As far as I can see, the position with regard to "Ethanesal" is as follows: Mackenzie Wallis claimed on successive occasions that "Ethanesal" contains "ketones comprising those in the middle of the series" (THE LANCET, June 4th, 1921, p. 1175) 2 per cent. and later 5 per cent. of methylethylketone (THE LANCET, March 3rd, 1923, p. 428). At the meeting on March 7th he stated again that "Ethanesal" should contain methylethylketone, and read the report of a well-known analyst, who had found ketones in "Ethanesal" to the extent of 1·3 per cent. In commercial "Ethanesal" we, like Dale and his colleagues, found no trace of ketones, but *N*. butylalcohol. (If *iso*butylalcohol had been added, methylethylketone might have been formed.) Now we find that if 5 per cent. of methylethylketone is actually added to purest ether, the mixture proves to be extremely toxic for animals, so that its use in therapeutics would be criminal.

I am, Sir, yours faithfully,

STORM VAN LEEUWEN,
Director of the Pharmacotherapeutical Institute
May 1st, 1924. of the University of Leiden, Holland.

TUBERCULOSIS OF THE LARYNX.

To the Editor of THE LANCET.

SIR,—Sir StClair Thomson's surmise, mentioned in your leading article last week, that "though it would be difficult to make a comparison of the nose and pharynx in sanatorium patients with an equal number of the healthy public . . . trouble in these regions is no more common in a sanatorium than out of it" is, of course, interesting. But what may well be coupled with this is the fact that of the dozen or so of those, from many countries, who *have* made the comparison in question—among them an eminent laryngologist like Moure of Bordeaux—all without exception record great preponderance of such nasal defect in the tuberculous. Sir StClair Thomson's finding that these lesions are not found more frequently in consumptives with laryngeal involvement than in other consumptives tallies with previous experience; and so, I fancy, would his comparison with the normal, were he to make one.—I am, Sir, yours faithfully,

Barnsley, May 3rd, 1924. W. C. RIVERS.

SMALL-POX AND VACCINATION.

To the Editor of THE LANCET.

SIR,—I fear that Dr. J. C. McVail pays the article I wrote in criticism of his address to Members of Parliament a greater compliment than it deserves by devoting five pages to his reply. I am gratified that he should have considered so carefully the various points raised by me, and would thank him for the fair and courteous manner in which he treats me.

Dr. McVail is, of course, a highly skilled and practised controversialist, whose knowledge on this subject is unrivalled. It was not to be expected that any weak, or apparently weak point, however small, in his opponent's case would escape detection. Moreover, he has not confined himself to my article in THE LANCET, but has evidently searched the record of my writings on this subject for the past 22 years pretty closely, and the few slips and inconsistencies that he is able to lay to my charge are not (I hope your readers will agree) very serious.

Many of the points at issue between us I am quite content to leave as they stand in our respective articles for your readers' judgment, but there are some upon which I should like to comment.

1. *Infant Vaccination.*—I am sorry if Dr. McVail thinks that I charged him unjustly with vagueness in the use of the term "vaccination." My complaint, which is against provaccinists as a class and not only against Dr. McVail, is that the term "vaccination" is often used in a different sense when advocating or defending vaccination. If, however, I was unjust in the case in point I regret it.

2. *The Story of Kilmarnock.*—I still think that it is unfair to quote the ravages of small-pox nearly two centuries ago as an argument to justify universal vaccination to-day. For the sake of comparison, suppose a proposition were before Parliament to make anti-typhoid inoculation universally compulsory. Would it be fair to quote the ravages of typhoid fever long ago as an argument for doing so? Surely not!

3. *The Vaccination Acts.*—Dr. McVail says that the question of compulsion or non-compulsion is not for doctors, as doctors, to decide, but for the legislature. Of course, I agree; I have never disputed it; but he goes on to say that "the duty of the medical profession is to inform Parliament and the public of the truth about vaccination, and its safety, and having done so to leave Parliament to deal with the law. . . . If Parliament disbelieves in vaccination it should repeal the Acts. If it believes in vaccination it should exercise some degree of pressure in support of its belief. . . ." (Dr. McVail must forgive me for not quoting the whole passage, but the question of space must be considered.) I should like to suggest that the expression "believes in vaccination," although it sounds so simple, is really

very vague, but I will let it pass. To me the statement recalls the practice of the Ecclesiastical Courts in the old days in trials for heresy. Having found the victim guilty, he was handed over to the "Secular Arm" to be appropriately dealt with. Any odium or responsibility for roasting the heretic then rested on the latter! I suggest that the real moral responsibility for compulsory vaccination rests with the medical profession and not with Parliament, and that it is owing to the manner in which the case for vaccination is presented to them by the medical profession that our legislators believe—sometimes even more strongly than the profession does itself—in the necessity for compulsion.

4. *Individual and Communal Protection.*—Dr. McVail says that the analogy I draw between the old practice of small-pox inoculation and the modern practice of vaccination is a false one because inoculation was infectious whilst vaccination is not. I submit that though vaccination may not be infectious, yet nevertheless it does tend, by masking the disease, to encourage the spread of small-pox, and therefore that the analogy is perfectly valid.

5. *Germany.*—Dr. McVail draws attention to the fact that my views as to the value of the German system of universal vaccination and revaccination have undergone some change. I admit the impeachment. In the light of Germany's unexpected experience with small-pox during the past few years I imagine that others besides myself have had to modify their ideas to some extent about the effectiveness of the German system. We used to think—at least we used to be taught—that owing to universal revaccination in Germany it was possible to dispense with special small-pox hospitals and that ordinary general hospitals could safely be used for such imported cases as might from time to time occur. I am beginning seriously to doubt this. I still believe as firmly as ever that if a whole community (without exception) be vaccinated and revaccinated *often enough*, that community has nothing to fear from small-pox; but I am beginning to doubt if it is really practicable to vaccinate and revaccinate a whole community, without exception, often enough. In any case it is rather a heavy price to pay. In the meantime, until we know a little more about the details of Germany's recent experience, I, personally, shall certainly not feel justified in quoting the German system so confidently as I did in 1911.

6. *Temporary Protection.*—Dr. McVail says that when I state that the immunity enjoyed by small-pox nurses is not evidence that infant vaccination protects the community I am denying "what no human being in his senses ever dreams of asserting." Whilst this may be literally true, nevertheless the argument from the immunity of small-pox nurses is used more often than any other to establish and support "belief in vaccination," and, that being accomplished, the need for infant vaccination is supposed to follow as a logical corollary. Indirectly, then, the immunity of small-pox nurses is certainly used as a strong argument for infant vaccination. (In this connexion I think that the antivaccinists are largely to blame. Most of them appear to base their case against vaccination on the ground that its supposed power to immunise against small-pox is a myth and a delusion. The provaccinists naturally reply by proving that it does immunise, and the immunity of small-pox nurses and doctors is the strongest possible evidence of this.)

7. *Absent Small-pox.*—Because I draw attention to the fact that small-pox prevalence and mortality have greatly declined during the past two decades, in spite of the simultaneous great decline in infant vaccination, Dr. McVail accuses me of adopting "one of the most obvious sophistries of the present-day antivaccinist." Here he does me a clear injustice. The antivaccinist asserts that "the less vaccination, the less small-pox." I have never done that. I agree, of course, with Dr. McVail that the true relationship is "the less small-pox, the less vaccination." But I do say—and I cannot think that Dr. McVail really differs from me in this—that such a conjunction, continued over a long period of years, enormously weakens the provaccinist claim that the reduced prevalence and mortality of small-pox are due, or even chiefly due, to infant vaccination.

8. *Tetanus and Vaccination.*—Under this heading Dr. McVail makes the most of two statements—neither of them at all material—once made by me on hearsay evidence, and which I afterwards admitted were erroneous. I do not complain. One cannot be too careful in verifying one's facts.

9. *Leicester.* (*a*) *Unfulfilled Prophecy.*—Dr. McVail complains that I have on several occasions (at least four) quoted his famous prophecy, published in "Vaccination Vindicated," when I have been referring to the Leicester experiment. I sincerely regret if my having done this has caused him any annoyance. I can assure him that I have quoted him so often solely because his prophecy, made in such a standard provaccinist text-book, so aptly and authoritatively expresses the view almost universally held by the medical profession when the Leicester experiment was begun as to what the result of the experiment would be. Such a quotation is valuable as proving the importance attached to the Leicester experiment at that time. Let me say further that I have not the slightest doubt that, had I then been a qualified medical man, I should myself have heartily endorsed Dr. McVail's prophecy which, in the light of the beliefs then held, was a perfectly reasonable and justifiable one. A more serious charge is that I have been guilty of "mangling" the passage in which the prophecy occurs. I admit that deliberately to cut out parts of a quotation with the object of distorting its meaning is a serious offence, but I suggest that all I have done was to shorten a rather lengthy passage by omitting a sentence (and indicating the omission) which I honestly considered was not material. Even with this omission the passage as quoted ran (in my book) to over 100 words. As regards his complaint that I have continued to give the abbreviated quotation since he took exception to it in his Milroy Lectures I can only say that it was unintentional. I read his Milroy Lectures, and very interesting they were, but either I overlooked this particular point, or had quite forgotten it. I will certainly be careful to observe his wishes in future and to give the passage in full.

(*b*) *The Method.*—I do not think that Dr. McVail is quite fair to me here, but will let it pass.

(*c*) *Mild Small-pox.*—I recognise that there is some justification for Dr. McVail's criticism of the statement in my book, "The Vaccination Question," p. 125, in which I attribute the progressive decrease in the fatality of the last four principal Leicester epidemics to the influence of sanitation, at least so far as the last two are concerned (between the second and third there was, as he points out, no appreciable reduction). If and when the book calls for a second edition I will modify the statement, and I thank Dr. McVail for drawing my attention to it, but the point has, of course, no direct bearing on my LANCET article.

In conclusion, may I express my warm personal regard for Dr. McVail, and my admiration and respect for his encyclopædic knowledge—the result of life-long study—of this question of small-pox and vaccination, especially on its historical side.

I do not think that there is really so much difference between us—at least not as regards fundamentals—as might appear on the surface. I, on my side, am inclined to think that the time has come when all that remains of compulsory vaccination might safely be discarded (in this country) and that some advantage would be gained thereby. He, on the other hand, does not think that that time has yet arrived, though he admits (in his Milroy Lectures) the possibility that it may come some day. Possibly I err on the side of over-confidence, or it may be that he is unduly cautious. Which view is right is for your readers to judge.—I am, Sir, yours faithfully,

Leicester, April 26th, 1924. C. KILLICK MILLARD

MYELOMA OF THE ALVEOLUS.

To the Editor of THE LANCET.

SIR,—In the last issue of THE LANCET Mr. P. B. Kittel reported an interesting case of myeloma in the upper jaw of a boy of 5½, commenting on the infrequency of this condition at that early age. By coincidence, a boy aged 13, has just been discharged from this hospital after operation for a similar condition. A small, warty growth appeared on the hard palate close to the alveolar margin some 12 months ago, since when it gradually increased in size. On admission there was a circular pedunculated papilloma about half an inch in diameter, with a smooth, flat, dark-red surface and rounded edge, growing apparently from the periosteum of the alveolar process between the first and second right bicuspid teeth, both of which were sound. X ray showed no osseous lesion. The tumour was freely excised by Mr. Arthur Cooke and on section showed the stroma and multinucleated cells typical of a myeloid sarcoma.

I am, Sir, yours faithfully,
ARTHUR B. SMITH, M.B., Ch.B. Edin.,
House Surgeon, Addenbrooke's Hospital,
May 5th, 1924. Cambridge.

MATERNAL MORTALITY IN CHILDBIRTH.

To the Editor of THE LANCET.

SIR,—To those of us who have been striving for the better education and training of the midwife, your leading article of April 19th with this title appears to give an entirely wrong impression of Dr. Janet Campbell's recent report (No. 25 of the Ministry of Health). Your article states: "Since the passing of the Midwives Act in 1902 it is a matter for regret that so little improvement, if any, has been noted in the maternal statistics. In a series of 256 unselected cases of puerperal fever recorded by Dr. Campbell, in an appendix to her report, it is noted that 102 cases occurred in the practice of midwives alone, as against 86 in which delivery was effected by a doctor"

What improvement in the maternity figures has taken place began at the beginning of this century, and though the Midwives Act came into force after then the improvement was maintained, reaching its maximum in 1917 to 1918, when the medical services were at their lowest and more work than usual was done by midwives. The disappointing high mortality of 1919 and 1920 was doubtless due to other causes than that of the type of the attendance on labour, and since then the figures have fallen near to the lowest level attained during the war.

The series of 256 odd cases from different districts given in Dr. Campbell's appendix, from which the conclusion is drawn that most cases occurred in the practice of the midwife, is particularly unjust. Those figures are clearly valueless for the purpose for which they are used. They are opposed to Dr. Campbell's own conclusion in regard to the relative responsibility of doctors and midwives, for she says: "There seems little profit, however, in attempting to apportion relative responsibility or blame" (p. 44). A much more reliable set of figures, given on page 32, are those of nearly 50,000 from the Q.V.J.I. midwives (undoubtedly a specially skilled body of women) with an average rate of 1·8 per 1000, or half the general rate for the country.—I am, Sir, yours faithfully,

Wimpole-street, W., May 6th. JOHN S. FAIRBAIRN.

DONATIONS AND BEQUESTS.—The late Mr. George Taylor Chadwick, of Harrogate, Yorks, left by will, among other bequests, £1000 to the Rochdale Infirmary.—The following bequest has been made under the will of the late Miss Amelia Halkett, of Ryde, Isle of Wight, and of Pitfirran, Fife: £1000, free of duty, to the Royal Isle of Wight Hospital to endow an "Arthur Halkett" bed or cot in the children's ward in memory of her nephew.—Miss Henrietta Emma Reeve, of Regent-terrace, N.W., left £2000 each to the Royal Free Hospital and to the Royal Hospital for Incurables, Putney; also £2000 to her medical attendant, Alfred Alexander Cummin Grant, in recognition of his kindness and attention to her late uncle, Charles Reeve, and herself.

Obituary.

FRANCIS WILLIAM CRAGG, M.D., D.Sc. EDIN.

BY the death on April 23rd from typhus, at the early age of 42, of Major F. W. Cragg, I.M.S., Assistant Director, Central Research Institute, Kasauli, the science of medical entomology has lost one of its ablest workers, and the Indian Medical Service a distinguished officer. It is tragic to recall that only a little more than two years ago this fell disease claimed as its victim another distinguished worker, Mr. A. W. Bacot. Details regarding the circumstances under which Cragg contracted the disease have not yet reached this country, but evidently he was deputed to investigate its ætiology (still a mystery) at Lahore, and, like Bacot, Cragg was alive to the danger of handling infective body lice, or coming into contact with lousy patients, but in some way at present unknown the virus passed into his system with fatal results. Every worker in this branch of experimental medicine knows only too well how easy it is to be bitten, or in some other way infected while handling large numbers of infective insects.

Francis William Cragg graduated M.B., Ch.B. in Edinburgh in 1905, and shortly after entered the Indian Medical Service. After a lengthy tour of military duty he came to Edinburgh on leave in 1910. He attended Prof. Ashworth's class of medical entomology and parasitology, giving much attention to zoological technique, and later under his direction took up the study of insect anatomy. His thesis for the degree of M.D., on "The Structure of *Hæmatopota pluvialis*," for which he was highly commended, is a model of descriptive anatomy. This piece of research was the foundation of Cragg's future work on medical entomology. Morphology, especially comparative morphology rather than systematic, was his bent, and he was a master of his subject. He was also deeply interested in the relation of insects to disease, and was well equipped to undertake research into the life-histories and methods of transmission of parasites. His knowledge of insect structure and of protozoology enabled him to avoid the many pitfalls in this particular line of research.

After returning to India in 1911 he applied for civil employ in the Jail Department, but soon found the work uncongenial, and then asked to be transferred to the Bacteriological Department. He was sent to the King Institute of Preventive Medicine, Guindy, Madras, where the writer first met him. At Guindy, with little routine work and unlimited material close at hand, Cragg was able to extend his knowledge of the comparative morphology of insects associated with or likely to be associated with disease-causing organisms. As a result of these researches he published a series of papers on "Studies on the Mouth Parts and Sucking Apparatus of the Blood-Sucking Diptera." These papers represent some of Cragg's best work on insect morphology, and show how quickly he arrived at an accurate interpretation of the mechanism of the parts studied. His beautiful line drawings enhance the value of these papers. At Guindy he also collaborated with the writer in several papers on descriptive entomology and bionomics, and one of these is the first paper in Volume I. of the *Indian Journal of Medical Research*. It was at Guindy that our joint work on "Medical Entomology" was conceived, planned, and carried out. Cragg's anatomical sections and his line drawings added greatly to the usefulness of the book as an introduction to the study of entomology. The completion of this work in about two years was only possible with Cragg's loyal coöperation.

In 1912, at his own request, Cragg was transferred to the Central Research Institute, Kasauli, where he continued to work until his death. It is possible here to mention only a few of his papers embodying original research of a high order in medical entomology; most of the papers will be found in the volumes of the *Indian Journal of Medical Research*. His studies of the reproductive system of *Cimex*, with special reference to the behaviour of the spermatozoa, attracted considerable attention. The discovery by the writer of the method of copulation in *Cimex*, and its demonstration to Cragg, led him to investigate the interesting and peculiar phenomena connected with fertilisation in the common bed-bug. This work of Cragg opens up an entirely new field of inquiry. His observations on the geographical distribution of the Indian rat-fleas as a factor in the epidemiology of plague is a valuable piece of work. If it is eventually proved that the rat-flea *Xenopsylla astia* plays no part in the spread of the bacillus of plague, then Cragg's work will be of the utmost value in the fight against plague in India.

In his studies of the spread of parasitic diseases Cragg soon recognised the importance of relapsing fever as a factor to be reckoned with in the mortality returns of India. His paper on relapsing fever in the United Provinces and Oudh focused attention on the disease. During his investigation at Agra he contracted relapsing fever, and had to take leave to this country. He went to Edinburgh and, although poor in health, worked again in the zoological department at several problems, and obtained the degree of D.Sc. in 1922. On his return to India towards the end of 1922 he set to work on several important problems connected with the bionomics of fleas, lice, and the bed-bug, and he looked forward later to return to the investigation as to whether the flea *Xenopsylla astia* plays any part in the transmission of the bacillus of plague. But this was not to be.

Major Cragg was a fearless investigator, and he gave promise of adding much to our knowledge on insects in relation to disease. His loss is irreparable. A cheery companion, he will be sorely missed by his many friends.

To Mrs. Cragg, who was not able to be with her husband in his last hours, and to his two fatherless children, the deepest sympathy of the medical profession will be extended.

W. S. P.

GRANVILLE STANLEY HALL, Ph.D. Harvard, LL.D.

Dr. G. Stanley Hall, President Emeritus of Clark University at Worcester, Massachusetts, who died on April 24th, was born in 1845 of that New England stock which carries almost no infusion of other than English blood, and his boyhood was lived in straitened circumstances, but among the traditions associated with a Puritan upbringing. Following upon a college education in America he was enabled by far-seeing friends to spend three years of study in Germany, and, after holding a professorship at Antioch College and doing tutorial work at Harvard, he made a second long visit to Europe when he studied under Wundt, Ludwig, and Helmholtz. Then followed a professorship of psychology and pædagogy at Johns Hopkins University, and in 1888 he became head of the newly formed Clark University at Worcester. The difficulties of this position, when loyalty to the founder demanded a silence on vital matters which for a time alienated Stanley Hall's personal friends as well as those American scholars who had been attracted by the academic ideals of the new foundation, have only lately been made known, but the faith of a few saved the venture, and on his retirement in 1920 he could look back with pride upon its achievements.

Although his name was known to only a small circle in this country, Stanley Hall stood as a pioneer of psychological study in America. He was the first President of the American Psychological Association, and founded the *American Journal of Psychology* and the *Journal of Applied Psychology*. Last year he published, under the title of "Life and Confessions of a Psychologist," an analytical autobiography which revealed how his study of mankind, of man's place in nature, his origin and destiny, had become to him a source of almost religious comfort. He is, perhaps, best known to us by his work on "Adolescence," which appeared in 1904, and still stands well above the flood of literature on that or kindred subjects. Though never losing interest in experimental psychology, he was already becoming impatient with scholasticism, and even then wrote scornfully of "a bankrupt psychology without a soul," whilst demanding that the study of the mind should make contact with life at as many points as possible. Psychology touches so many of our beliefs and prejudices that he inevitably raised bitter criticism. He speaks in his "Life and Confessions" of the *odium sexicum* roused by his pre-analytical work on "Adolescence," and when he turned to psychoanalysis as to a new dispensation in normal psychology he was for more than a decade, as he expresses it, little more than *vox clamantis in deserto*. He himself regarded his best work as being the elaboration of the genetic view of mental development; introspectionists, behaviourists, and anti-psychoanalysts were for him in the pre-evolutionary stage through their failure to appreciate that the soul is as much a product of evolution as the body.

The *American Journal of Psychology* so recently as last January spoke of "this modern Aristotle," and expressed the hope of his former students and the friends of learning everywhere that he would be spared to finish those volumes he contemplated to complete his system. But Stanley Hall had already shown a calm expectation of the end when, after setting out his desire to accomplish something really worth while in the world, he wrote: "Yet all the time I know that the Supreme Queller may at any time now intervene and cut down all these aspirations as the mower does the last lush crop of rowan before the snow and ice of winter kill it at its very roots."

CHARLES ROBERT GRAHAM, M.R.C.S. Eng., L.R.C.P. Edin.

It was with great regret that the public of Wigan and surrounding districts heard of the death of Dr. C. R. Graham at the age of 67. Dr. Graham for over 40 years conducted an extensive practice in Wigan, and in 1919 he retired to Bolton-le-Sands, near Carnforth, where his death occurred on April 27th. After a general education at Wigan and Annan, he studied medicine at Owens College, Manchester, and at Paris, taking the M.R.C.S. Eng. and L.R.C.P. Edin. in 1878. Before commencing practice in his native town of Wigan, he acted as senior house surgeon at the Royal Berkshire Hospital, Reading, and as resident medical officer at the Hospital for Children at Pendlebury, Manchester. For 34 years he was one of the honorary surgeons to the Royal Albert Edward Infirmary, Wigan, and for other seven years was consulting surgeon to the same institution, thus establishing a record of 41 years' association with the Wigan Infirmary. For many years he acted as one of the surgeons of the Lancashire and Cheshire Miners' Permanent Relief Society and as medical adviser to other societies. He was a keen and expert angler and was regarded as an authority on fly-fishing. Dr. Graham leaves a widow, three daughters, and a son. One daughter and his son are members of the medical profession. Dr. Graham was held in the highest esteem in Wigan, and to many his death will come with a keen sense of personal loss.

EDWIN BEATON, M.D. Camb.

Dr. Beaton, who died of pneumonia in Cairo at the early age of 43, was bacteriologist to the Public Health Department in that city. Son of the late Mr. Edwin Beaton, formerly chief constructor at the Admiralty, he was educated at Caius College, Cambridge, going on to St. Mary's Hospital. He took his Conjoint Board Diploma in 1906 and his medical degree at Cambridge in 1909. In 1923 he took the M.A. and M.D. degrees. After filling one or two house appointments at St. Mary's Hospital he joined the staff of the inoculation department, where he worked until, a few months before the war, he was appointed to the laboratory staff of the Egyptian Public Health Service under Dr. Charles Todd. He continued in this service until his death. A colleague writes from the inoculation department, St. Mary's Hospital: "Edwin Beaton was held in affectionate regard by all those who worked with him here—and no less, as we well know, by his colleagues in Egypt. He joined us in 1910, and set to work on problems connected with the antitryptic power of the blood, which was just then beginning to attract attention. After much careful work on the elaboration of accurate micro-methods of measuring this function of the serum he applied these to the study of a great variety of pathological conditions. Probably he was the first to recognise the important fact that an increased antitryptic power is associated with every infection. Unhappily, he was too little anxious to publish his work—an expression of his very reserved nature—and in consequence a great many valuable observations lie buried in his note-books."

Throughout the war Beaton was kept fully occupied with the routine public health work of his department, but with the return of peace conditions he again turned his attention to the nature of the antitryptic power, publishing his observations in the *British Journal of Experimental Pathology* (1922, iii., 224). His M.D. thesis (not yet published) makes a further contribution to the same subject.

ARTHUR JOHN NYULASY, L.R.C.P. EDIN., M.R.C.S. ENG.

Dr. Nyulasy, who died recently at his brother's house in Melbourne, was well known as a surgeon and gynæcologist in Western Australia. He started life with the intention of becoming an engineer and obtained his certificate as surveyor before entering the Melbourne Medical School. He completed his medical studies at various centres in Europe, qualifying L.R.C.P. Edin. in 1890, and taking the English Conjoint qualification in the following year. Returning to Australia, he became assistant to his brother, Frank, at Toorak, Melbourne, migrating later on account of his health to Perth, where he built up a large general practice. He first attracted notice by a successful investigation into the origin of an epidemic of typhoid then prevalent in the district. During the South African War he served as medical officer with the contingent from Western Australia, and on his return was elected to the staff of the Perth Hospital, where he became in succession out-patient surgeon, surgeon, out-patient gynæcologist, and gynæcologist. Dr. Nyulasy retained throughout life his interest in anatomical study, and from the time of the Australasian Medical Congress in 1908 made it his endeavour to establish the view that the primary supports of the uterus are its ligaments, the pelvic diaphragm acting as a secondary support to prevent undue stretching of the ligaments from intra-abdominal strain. He took much time and trouble to familiarise his colleagues in Australia with recent advances in gynæcological technique. He stood for early operation in pelvic septic phlebitis, holding that serious cases of puerperal infection might be saved by early excision of the thrombosed veins. He was an advocate of the intestinal route of drainage in septic peritonitis, and recorded in our own columns in 1915 a series of six cases successfully so treated. He also described an original method of treating prolapse of the female bladder.

Dr. Nyulasy was a man of artistic tastes with some ability as a musician, whose loss leaves a gap among a large circle of medical and other friends in the Commonwealth. His death was due to malignant disease of the stomach, borne with great fortitude.

Medical News.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—At a meeting of Comitia on April 24th licences to practise were conferred upon the following candidates who have passed the Final Examination of the Conjoint Board :—

S. Abadir, King's Coll.; A. H. Abdel-Messih, Cairo and Manchester; M. C. V. Abraham, Manchester; J. N. Alexander, Guy's; H. G. Anderson, St. Bart.'s; J. H. Anderson, Manchester; F. Asker, R. T. Bannister, and V. Barkin, St. Bart.'s; P. Bauwens, St. Thomas's; Margarida R. Bensaude, Birmingham; M. Bersinski, Middlesex; H. B. Boucher, St. Thomas's; W. H. Bradley, Oxford and Guy's; R. A. Brews and S. G. Brown, London; J. R. Burrows, Liverpool; Edna V. Butler, Bristol; L. W. Cann and R. J. Cann, Guy's; J. A. Carman, London; A. M. Claye, Leeds; H. G. Close, Guy's; G. E. C. Collis, Univ. Coll.; R. F. Connell, Middlesex; Elizabeth M. Cowie, Royal Free; D. V. Davies, St. Thomas's; G. I. Davies, Univ. Coll.; Gwladys D. Davies, King's Coll.; E. C. Dawson, Birmingham; J. R. B. Dearden, Cambridge and St. Bart.'s; C. J. C. de Silva, Liverpool and Middlesex; C. H. Devereux, Univ. Coll.; B. Dous, St. Bart.'s; Ethel Downing, Royal Free and St. Mary's; E. F. Duck, Univ. Coll.; W. L. Dunlop, Liverpool; W. H. du Plessis, St. Thomas's; Kathleen H. Durance, Royal Free; L. C. Edwards, London; W. S. D. Elder, St. Andrews and St. George's; C. L. Elgood, Oxford and St. Bart.'s; A. Elliot-Smith, Cambridge and Univ. Coll.; S. W. Eveson, London; H. B. Flooks, Cardiff and Guy's; J. H. Francis, Cambridge and St. Mary's; A. T. Fripp, Oxford and Guy's; E. B. Garrett, Univ. Coll.; A. Gilberg, Middlesex; J. F. Goodenough, Guy's; C. A. H. Green, Oxford and St. Bart.'s; J. L. Griffin, Bristol; N. W. Hammer, Middlesex; I. Harris, Cardiff and Westminster; Greta Hartley, Royal Free; H. N. Hearle, Guy's; F. Heckford, St. Bart.'s; E. F. Hewlitt, Guy's; R. A. Hickling, Westminster; Florence R. Hodges, Royal Free and St. Mary's; Barbara M. Hope, King's Coll.; Margaret Hossell, Royal Free; L. W. Houghton, Guy's; D. V. Hubble, St. Bart.'s; M. W. P. Hudson, St. Thomas's; W. S. Hunt and I. M. Hurwitz, Guy's; Dorothy P. Hytch, Royal Free; E. Jacobson, Cape and London; J. P. W. Jamie, Cambridge and St. Bart.'s; D. Jones, London; D. S. M. Jones and H. M. R. Jones, Middlesex; I. S. Jones, Liverpool; R. Jones, Birmingham; A. Jowell, Cape and Guy's; Dorothy L. M. Keats, Royal Free; H. N. C. van G. Kelaart, Ceylon; A. C. King, London; F. H. King, Cambridge and St. Bart.'s; J. H. Kok, Utrecht and Middlesex; R. Langford, Cambridge and London; O. B. Lean and H. Lord, Univ. Coll.; Elsa P. Lunn, Birmingham; W. J. E. Lupton, Oxford and St. George's; E. M. McCausland, Middlesex; Lily C. MacKinnon, Charing Cross; W. W. McLean, Cambridge and St. Thomas's; J. G. McMenamin, St. Bart.'s; D. Magrath, Birmingham; Dorothy B. Marling, Royal Free and London; D. G. Martin, St. Bart.'s; W. A. Mill, Guy's; K. F. T. Mills, Cambridge and Middlesex; G. G. Milne, London; S. M. Milner, Cambridge and Manchester; W. E. Moody, Bombay and St. Mary's; G. O. Morgan, Cardiff and King's Coll.; E. G. Morris, Cambridge and St. Thomas's; Ethel W. Morris, London; L. N. Moss, Cambridge and St. Mary's; B. S. Mote, Bombay; G. Murray Shirreff, Bristol; M. Nazmi, Cairo and Univ. Coll.; E. V. Newling, Middlesex; Nancy B. Ockenden, Univ. Coll.; Doris M. Odlum, Royal Free and St. Mary's; G. F. S. Parker, Manchester; K. O. Parsons, Guy's; E. A. T. Pateman, Calcutta and Charing Cross; J. N. D. Paulson, Edinburgh and St. Mary's; J. F. Payan, Guy's; T. Peirson, Manchester; A. Perkoff, London; E. B. Pollard, St. Bart.'s; Winifred M. Proctor, Durham; Eleanor M. Pulleine, Royal Free and St. Mary's; F. K. B. Quanbrough, Bombay and St. Bart.'s; G. Ralston, London; M. A. Rana, Punjab and St. Mary's; R. H. T. Rea, Cambridge and St. Thomas's; T. S. Read, Cambridge and King's Coll.; Dorothy M. Rees, King's Coll.; E. J. Rees, Cardiff and St. Thomas's; C. B. Rich, Charing Cross; W. M. Roberts, Manchester; F. Robinson, Durham and Manchester; R. E. Robinson, Guy's; Dorothy W. Roughton, Royal Free and London; F. E. E. Schneider, Univ. Coll.; M. B. Seng, Guy's; T. H. Sims, Cambridge and St. Thomas's; I. Spiro, Liverpool and Univ. Coll.; C. R. Steel and G. G. Stewart, St. Bart.'s; M. H. Steyn, Amsterdam and St. Thomas's; G. E. F. Sutton, King's Coll.; H. Taylor, London; J. H. G. Thompson, Cambridge and St. Thomas's; P. H. T. Thorlakson, Manitoba; W. G. Thwaites, St. Thomas's; R. J. Toleman, Cardiff and London; A. Tom, Guy's; Mary M. Turnbull, King's Coll.; Cicely N. Twining and Hermione M. Usborne, Royal Free; G. M. Wadsworth, Leeds; J. L. Warner, Cambridge and Middlesex; P. B. Wilkinson and T. M. Wilks, King's Coll.; D. H. Williams, London; G. Williams, St. Mary's; Dorothy Wood, Charing Cross; T. E. W. R. Wood, B. H. H. Wooderson, and H. G. Wyatt, London; and Z. M. Yusuf, St. Bart.'s.

Diplomas in Tropical Medicine and Hygiene were granted, jointly with the Royal College of Surgeons of England, to the following candidates :—

Monawar Khan Afridi, Edward H. Black, Surendranath E. Borah, Clifford V. Braimbridge, Nariman Hormusji Clubwala, Anant Yashwant Dabholkar, Mary Ellison, Lily G. Iliff, John G. Johnstone, Frederick Stevenson, and Edward S. Walis.

Society of Apothecaries of London.—At examinations held recently the following candidates passed in the subjects indicated :—

Surgery.—H. L. Bernstein, Guy's Hosp. ; P. V. Casling, St. Mary's Hosp. ; E. J. R. MacMahon, St. Thomas's Hosp. ; I. Morgan, St. Mary's Hosp. ; W. T. Swanton, Univ. Coll., Cork, and Charing Cross Hosp. ; and W. J. Wood, University of Leeds.

Medicine.—F. Beinaschewitz, University of Bern ; R. Hare, St. Mary's Hosp. ; W. M. Jones, St. Bart.'s Hosp. ; J. N. Wheatley, London Hosp. ; and W. J. Wood, University of Leeds.

Forensic Medicine.—W. B. Arnold, St. George's Hosp. ; A. J. M. Davies, St. Mary's Hosp. ; J. Herbert, Guy's Hosp. ; W. R. S. Jaecques, Louvain and Ghent ; and J. N. Wheatley, London Hosp.

Midwifery.—E. H. Boodrie, St. Mary's Hosp. ; W. R. S. Jaecques, Louvain and Ghent ; A. Kotbi, St. Mary's Hosp. ; D. G. Robinson, Guy's and Charing Cross Hosps. ; and G. H. Shanley, Durham.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery : P. V. Casling, W. M. Jones, E. J. R. MacMahon, I. Morgan, D. G. Robinson, J. N. Wheatley, and W. J. Wood.

Royal College of Physicians of Edinburgh, Royal College of Surgeons of Edinburgh, and Royal Faculty of Physicians and Surgeons of Glasgow.—The following candidates have passed the Triple Qualification Examination and have been admitted as licentiates :—

Wilfred A. Bartholomeuz, Douglas M. Beaton, John S. Caldwell, Matthew Clouts, John C. Colvin, James Courtney, Charles J. Coventry, Frederick W. Duthie, Herbert M. Hobson, Bruce F. Home, William D. Howat, John A. A. Hunter, Morris Kelman, Douglas J. Kynoch, Douglas D. O. M'Loughlin, Harry Myers, George C. Philips, William J. Rankine, Frederick W. Robinson, Israel Rostowsky, Robert D. Scorgie, Geoffrey H. Sellers, and Annie H. Sutherland.

University of Glasgow.—At the graduation ceremonial on April 23rd the following degrees were conferred :—

M.D.—Margaret H. Grant (with commendation), John M. W. Morison (with commendation), Thomas D. Miller, and Elaine B. S. Stocquart.

M.B., Ch.B.—With honours : William Thomson, Henry S. Russell, and David Hynd. With commendation : Andrew S. Barr, Francis D. Morphy, John Montgomery, Thomas A. Fyfe, John C. Alexander, Robert Graham, Adam D. Mack, Robert A. Kennedy, Archibald Brown, James Ross, John G. M'Whirter, James Morison, Hector Macdonald, Charles M. Brown, Robert Black, John A. M'Gregor, James M'Fadzean, Kenneth A. Mackay, James C. Gillies, Robert G. Cochrane, and John Adam.

Robert H. Abercrombie, William G. Allan, Margaret M. Allison, Janet H. Anderson, John Anderson, William C. Armstrong, William G. Arthur, John W. Baxter, Samuel Baxter, Mary V. F. Beattie, John Beck, John S. Bell, Marion H. Black, Andrew Bowie, Janet S. Brooks, Alexander Brown, Andrew Brown, David K. Bruce, James Caldwell, Alexandrena F. Cameron, Douglas Cameron, Duncan MacG. Cameron, Robert M. Chalmers, George Collier, Hew B. Cordiner, Arthur L. Cowan, James Crawford, Janet I. A. Cullen, John Cumming, Donald E. S. Cunningham, Robert E. Davie, Slavoljub S. Djordjevitch, Robert S. Doig, Robert S. Donaldson, Lily S. Duncan, George H. Edgecombe, Norman F. Edgecombe, Harold Fairbairn, Christina G. Findlater, Donald MacD. Fraser, Thomas Fulton, Finlay MacR. Fyfe, Lachlan H. Gilchrist, William Gilchrist, William Gillespie, William N. M. Goldie, Oliver Gray, Robert A. Gray, Andrew A. Grierson, Gordon L. Grieve, Reginald K. Hanlin, David M. Harper, William A. Harper, Thomas Heffron, John D. Hempseed, Gertrude Henderson, Mary Hendrie, John W. M. Humble, Alexander M. Innes, George C. Kelly, Duncan L. Kerr, Hugh F. Kerr, Ralph A. W. Wilson, Sarah B. Wilson, Ruby E. Winning, Robert M. Wylie, Ida Wyllie, and James W. Young.

The Prince of Wales has become Patron of the London Homœopathic Hospital, Great Ormond-street, W.C., and the Duke of York President, in succession to Lord Cheylesmore, who becomes Vice-President.

Medical Prayer Union.—The annual medical missionary breakfast will be held on Wednesday, May 14th, at the Refectory, University College, Gower-street, W.C., at 8 a.m., under the presidency of Mrs. Scharlieb, M.D. An address will be given by Dr. J. A. Liley, of Tangier. An intimation of intention to be present will be welcomed by Dr. Tom Jays, the hon. secretary, Livingstone College, Leyton, E. 10.

Medico-Psychological Association.—The next quarterly meeting of the Medico-Psychological Association of Great Britain and Ireland will take place on May 22nd, at 11, Chandos-street, Cavendish-square, London, W., under the presidency of Lieut.-Colonel E. Goodall, at 2.30 p.m. Dr. J. Carswell will deliver the Fifth Maudsley Lecture at 3 p.m., at the House of the Royal Society of Medicine. The subject of the lecture will be Some Sociological Considerations bearing upon the Occurrence, Prevention, and Treatment of Mental Disorders.

Royal Institution.—The annual meeting of the members of the Institution was held at Albemarle-street on Thursday, May 1st, Sir James Crichton-Browne, Treasurer and Vice-President, in the chair. The annual report of the committee of visitors for the year 1923, testifying to the continued prosperity and efficient management of the Institution, and the report of the Davy Faraday Research Laboratory Committee, were read. It was stated that 53 new members were elected during the year, and 63 lectures and 18 evening discourses were delivered. Sir James Crichton-Browne was re-elected as treasurer, and Sir Arthur Keith as secretary. The board of managers includes Dr. J. Mitchell Bruce, Mr. Ernest Clark, and Sir Charles Parsons.

Central Association for Mental Welfare.—A conference on Mental Deficiency will be held in the Central Hall, Westminster, London, S.W., on Wednesday and Thursday, May 28th and 29th. At the morning session on Wednesday (10.30 a.m.), Sir Leslie Scott, M.P., in the chair, an inaugural address will be given by Mr. J. Wheatley, Minister of Health, followed by papers on the Best Methods of dealing Administratively and Educationally with the Mentally Defective (Feeble-minded) Child, by Dr. H. B. Brackenbury and Mr. E. Salter Davies, and at the afternoon session (2.30 p.m.) by Dr. H. Herd. On Thursday, at 10.30 a.m., Dr. W. A. Potts will be in the chair, and a paper on the Influence of Heredity and Environment in Causing Mental Deficiency will be read by Dr. A. F. Tredgold. In the afternoon, at 2.30, a paper and address on Mental Tests—their Value to the Medical Officer, the Educationalist and the Social Worker, will be given by Dr. Cyril Burt and Dr. Robert Hughes, with the Rev. Principal Thomas in the chair. At each session there will be a discussion on the papers read.

The late Dr. H. A. Bull.—Harry Ashworth Bull, L.R.C.P. Lond., who died in a London nursing home on April 19th at the age of 52, after an operation, was a well-known practitioner of Great Haywood, Staffordshire. He was surgeon to the Rugeley District Hospital, and in 1901 was appointed public vaccinator for the Colwich District of the Staffordshire Union, and later took over the duties of medical officer for that area. He was also medical officer of the Sister Dora Convalescent Hospital at Milford. Keenly interested in any kind of public work which had a medical bearing, Dr. Bull was a prominent figure at meetings of tuberculosis and insurance committees, where his medical knowledge was always an asset in the debates. He was a member of the Staffordshire County Council, the Staffordshire, Wolverhampton, and Dudley Joint Tuberculosis Committee, the Staffordshire Insurance Committee, and the Staffordshire Mental Hospitals Board, and was a representative governor of the county grammar school. During the late war Dr. Bull was employed at the German prisoners' camp at Brocton, and the ill-health by which he had been handicapped for some time probably dated from this period of strenuous work. He leaves a widow, a son, and two daughters.

Medical Golfing Society.—In the final of this Society's "knock-out" tournament, Mr. Murray Thomson defeated Mr. T. P. Kolesar 2 and 1. The other semi-finalists were Dr. Cyril Ilott and Dr. T. B. Jobson.

League of Remembrance (1914–1919).—A meeting of the Medical Advisory Board of this League will be held at 1, Marlborough Gate, London, W., on May 13th, at 5 P.M., when Princess Beatrice will preside.

Dr. Hubert J. Norman will deliver an address on Insanity and Conduct at a meeting of the Ethological Society to be held at 90, Buckingham Palace-road, London, S.W., on Monday, May 12th, at 8.30 P.M.

West Kent Medico-Chirurgical Society.—A meeting will be held at the Miller General Hospital, Greenwich, on Friday, May 16th, at 8.45 P.M. Dr. E. G. Annis, the President, will occupy the chair, and will deliver an address entitled Old-fashioned Epidemics. A smoking concert will follow.

Chadwick Public Lectures.—To-day (Friday), May 9th, at 5.15 P.M., Prof. MacBride, F.R.S., will give a lecture on "Some Causes of a C 3 Population." The lecturer will describe the theory of mutations, and make suggestions as to causes of abnormalities which may be operative in producing C 3's. This lecture will be given in the Hall of the Royal Society of Arts, John-street, Adelphi. Dean Inge will take the chair. The history and present position of Women in Dangerous Trades will be set forth by Miss Constance Smith, H.M. Deputy Chief Inspector of Factories, on May 27th, at 8 P.M., in the Lecture Hall of Bedford College, Regent's Park, London, N.W. The last lecture of the programme will be given in the Chelsea Physic Garden, Swan Walk, Chelsea Embankment, on June 4th, at 5 P.M., by Sir David Prain, on Economic and Hygienic Relationships of Cinchona Bark and Quinine. Further information about Chadwick Lectures may be obtained of the Secretary, Mrs. Aubrey Richardson, at the offices of the Trust, 13, Great George-street, Westminster, London, S.W.1.

British Empire Cancer Campaign.—On Tuesday, May 6th, a meeting in support of the campaign was held at the Mansion House, London. The Lord Mayor, who was in the chair, announced that a special effort would be made in the City of London to provide a substantial addition to the funds of the campaign now available for cancer research. The Duke of York appealed for unremitting effort in combating the scourge which probably throughout the world accounts for more than half a million deaths annually. Sir John Bland-Sutton said that independent workers should be given facilities for work in established laboratories, and that the money which was given to help fight the cause of cancer would enable experts to be freed from the cares of practice and to devote their time to research. Prof. W. S. Lazarus-Barlow was of the opinion that the work would proceed along the lines of radium and X ray treatment, and he mentioned the curious power which existed in certain persons suffering from cancer to hold it in equilibrium for a number of years and on rare occasions to conquer it. Mr. J. Beaumont Pease said that £84,000 had already been subscribed, including an anonymous donation of £20,000 to meet expenses, so that the money subscribed by the public might be directly devoted to the campaign. Mr. J. P. Wheatley said that from inquiries made by the Ministry of Health in urban districts, they knew that not more than 50 per cent. of the people afflicted with cancer applied for treatment at all and that many others only applied when they were inoperable, and he urged the importance of preventive work. Lord Cave, Chairman of the Grand Council, said that they wanted to support all institutions which were studying the problem.—Among recent gifts to the British Red Cross Society for its campaign against cancer is the sum of over £279, the proceeds of the sale of the lathes and tools from the late Lord Hotham's private workshops. The British Red Cross Society has also received two anonymous gifts totalling £1500 and several donations of £100. Gifts to the campaign fund may be sent to the Hon. Sir Arthur Stanley, 19, Berkeley-street, W.1, cheques being made payable to the British Red Cross Society, and crossed "British Empire Cancer Campaign."

Queen Charlotte's Maternity Hospital.—On Monday, April 28th, Lord Howard de Walden presided at the annual meeting of this hospital, when it was announced that a Supplemental Charter of Incorporation had been granted by which the name of the hospital was changed from Queen Charlotte's Lying-in Hospital to Queen Charlotte's Maternity Hospital, and women became eligible for election on the committee of management. Lady Howard de Walden, Mrs. M. E. Christie-Miller, Mrs. Ernest Dent, and Mrs. Walter Seligman were among the first to be elected members of the committee. The annual report shows that while there is some improvement in the financial position much remains to be done before the hospital is free from debt. The number of patients admitted to the wards during 1923 was 1936 as compared with 1820 in 1922, while the patients visited in their own homes by the hospital midwives and medical officers numbered 2132 as compared with 2173 in 1922. The report refers to the gratifying fact that there were no maternal deaths among "district" out-patients during the year. In moving the adoption of the report, Lord Howard de Walden said that there had been an increased number of patients during the year, a large number of whom were emergency cases. He had hoped that the governors would have been able to enter on a rebuilding scheme, but they had found the difficulties greater than they had anticipated. To reduce the large overdraft at the bank the committee were reluctantly obliged to borrow £8000 secured on the hospital freehold, and it now amounted to £6540. They would have to do their best to raise the balance, and the committee wished to point out that the hospital was still in debt to the amount of £17,000. The report was adopted.

Manchester Hospitals and their "Outside" Patients.—An interesting question is being discussed in the Manchester local press as to whether too large a proportion of the beds in the voluntary hospitals are allocated to patients coming from outside the boundaries of the City of Manchester and the Borough of Salford. From the published statistics, the return for 1922—the latest available data, it appears that the total number of cases treated in Manchester and Salford hospitals was 262,208, and of these 40,629 cases came from outside areas—i.e., about 1 to 6·5—which proportion, it is stated, the hospital authorities do not regard as excessive, having regard to the fact that a very large number of the 40,000 are what are called specialist cases sent to the local hospitals for special treatment. There is, however, another aspect of the question—viz., the financial one. Do these "outside," and in some cases distant, districts from which these patients come contribute adequately for the treatment which such patients receive? The 1922 report shows that the expenditure for all the local hospitals was £341,288, while the corresponding ordinary income was £288,854, leaving a deficit for that year of £52,434. The cost to the local hospitals of the 40,000 "outside" cases was £95,735 and the corresponding contributions £44,461, leaving a deficit of £51,274, so that of total deficit of £52,434, £51,274 was due to patients sent from outside districts, while Manchester and Salford paid for their own patients except to the amount of £1159. Although through local efforts substantially increased contributions have been obtained from the outlying districts in Lancashire and Cheshire, in view of the above facts, if outside patients are to come to the local hospitals in such proportions, it is urged that something must be done to secure much more liberal contributions from these districts.

Parliamentary Intelligence.

HOUSE OF COMMONS.

Tuesday, April 29th.

The Tuberculosis Order 1914.

Sir **Thomas Inskip** asked the Minister of Health whether he intended to revive the Tuberculosis Order of 1914 (Order, No. 883, dated June 23rd, 1914, which was suspended by Order, No. 1215, of 1914), in view of the urgent necessity of enabling local authorities to take adequate steps to combat the disease of tuberculosis.

Mr. **William Jowitt** asked the Minister of Agriculture whether, in view of the large payments contributed by the Exchequer to schemes in connexion with tuberculosis and in view of the fact that infection was largely due to bovine tuberculosis, he would consider the advisability of bringing into force the Tuberculosis Order, 1914.

Mr. **Buxton** replied: I am giving careful consideration to the question of reintroducing the Tuberculosis Order of 1914, but I am not yet in a position to make a statement on the subject.

R.A.M.C. Officers' Leave at Woolwich.

Mr. **Penny** asked the Secretary of State for War whether he was aware that leave to the medical officers of the Royal Army Medical Corps in the Woolwich district had been stopped owing to shortness of staff, and that much discontent had been caused thereby; and what steps were being taken to rectify and overcome the great lack of candidates for this important arm of the service, the present conditions of which were not considered sufficiently attractive.—Mr. **Walsh** replied: No leave of officers of the Royal Army Medical Corps at Woolwich has been stopped, but three officers have had their leave postponed for a short period owing to sickness or other causes. As regards the last part of the question, I can assure the hon. Member that the matter is receiving careful consideration, although I am unable to make any statement at present.

WEDNESDAY, APRIL 30TH.

Flogging in the Navy.

Mr. **THOMAS JOHNSTON** asked the Civil Lord of the Admiralty if flogging had been re-established in the Navy for certain offences: if he was aware that flogging was dismissed as no satisfactory deterrent in the Report on Juvenile Delinquency, 1920; and if he would consult with some persons eminent in psychology, physiology, and in the dealing with youthful offenders, such as a London stipendiary magistrate, before he longer permitted a continuance of this practice.—Mr. **AMMON** replied: Boys convicted by court martial of certain serious offences are punished by birching. After careful inquiry I am satisfied that it would not be an advantage to abolish the punishment.

Mr. **JOHNSTON** asked whether the careful inquiry had included a report on the subject by Dr. James Glover, an eminent authority on psychology, and, if not, would the hon. gentleman consider that report if he sent him a copy.

Mr. **AMMON**: I have already stated that on my own initiative when I went to the Admiralty I went into this matter with the intention of seeing if flogging could be abolished. After going fully into the case and taking evidence I came to the conclusion that on the whole such abolition would be disadvantageous.

Viscount **CURZON**: Is it not the fact that the birch for the flogging of boys in the Navy has never been used except for serious sexual offences and that there is no feeling whatever on the part of the lower deck about it.

Mr. **AMMON**: I have already stated that it is only for very serious sexual offences, and there have only been six cases since 1917.

THURSDAY, MAY 1ST.

Royal Commission on National Insurance Terms of Reference.

Sir **KINGSLEY WOOD** asked the Prime Minister the terms of reference of the Royal Commission to inquire into national insurance, and the names of the members of the commission.—Mr. **WHEATLEY** replied: The following terms of reference have been agreed with representatives of the medical profession and the committee appointed for the purpose by the Approved Societies Consultative Council:—"To inquire into the scheme of National Health Insurance established by the National Health Insurance Acts, 1911–1922, and to report what, if any, alterations, extensions or developments should be made in regard to the scope of that scheme and the administrative, financial and medical arrangements set up under it." I am not yet in a position to announce the names of the members of the Commission.

The Germ of Foot-and-Mouth Disease.

Mr. **MACFADYEN** asked the Minister of Agriculture whether he had any information as to the alleged discovery by two German investigators, Dr. Dahmer and Prof. Frosch, of the germ of foot-and-mouth disease.—Mr. **BUXTON** replied: Such information has been received, and it is understood that full details as to these investigations will be published in the near future.

Recreation for Elementary School-children.

Mr. **EDMUND HARVEY** asked the President of the Board of Education whether he was able to take any fresh steps to encourage local education authorities in urban areas to make fuller provision for organised recreation for the children in elementary schools by acquiring new playing fields and by the better use of existing opportunities, and, in particular, for the utilisation of municipal tramways to convey scholars to parks, playing fields, and swimming baths at hours when the tramcars are not fully used by the travelling public.—Mr. C. **TREVELYAN** replied: Local education authorities are, I think, aware that the Board are quite prepared to encourage the activities mentioned by my hon. friend. I am always prepared to consider suggestions for their more extensive development.

Part-time Medical Officers of Prisons.

Lieut.-Col. **FREMANTLE** asked the Secretary of State for the Home Department (1) which were the prisons staffed by part-time medical officers: what were the present salaries of these officers; and on what basis were they arrived at. (2) In what respect had the closing of prisons increased the work and responsibility of the part-time medical officers at the remaining prisons; and whether it was proposed to increase their remuneration accordingly.—Mr. **HENDERSON** replied: The prisons and salaries are as follows:—Manchester, £300; Hull, £250; Winchester, Newcastle, Bristol, Cardiff, Lincoln, Preston, Durham, Borstal, Aylesbury, and Portland, £200 each; Leicester, Swansea, Shrewsbury, Portsmouth, Gloucester, Nottingham, Norwich, Exeter, Bedford, Wakefield, Oxford, and Dorchester, £150 each; Ipswich, Shepton Mallet, and Plymouth, £100 each. In fixing the salary the population of the prison is the basis, unless there are some special features justifying special consideration. The closing of eight prisons in March, 1922, has caused some increase in the population of some of the remaining prisons, and in one instance the salary of the part-time medical officer was increased. In the remainder the additional population has not so far been sufficient to justify an increase, but except where there has been an increase of this or other special grounds a temporary bonus is drawn.

Workmen's Compensation Medical Referees.

Mr. **THOMAS WILLIAMS** asked the Secretary of State for the Home Department if he was aware that the registrar of a county court in Yorkshire was appointing as medical referees under Section 11 of the Workmen's Compensation Act, 1923, doctors who were permanently employed as compensation doctors for certain coal-owners and the Yorkshire Coal-owners' Mutual Indemnity Company, Limited, to adjudicate in cases of dispute between other Yorkshire coal-owners whose workmen were insured by the Yorkshire Coal-owners' Mutual Indemnity Company, Limited, and workmen; and, as this had been brought to the notice of the registrar without result, would he inquire into the same and give instructions that medical referees appointed under Section 11 should in no case be doctors who were employed permanently by either coal-owners, coal-owners' mutual indemnity companies, or trade-unions affected.—Mr. **HENDERSON** replied: I am not aware of any such case. In the only instance brought to my notice it appeared on inquiry that the allegation was not borne out. It is a condition of the appointment of a medical referee that he shall hold no permanent employment of the kind referred to in the question.

MONDAY, MAY 5TH.

Plague in the Punjab.

Mr. **WARDLAW-MILNE** asked the Under Secretary of State for India if he would give the House any further information regarding the outbreak of plague in the Punjab.—Mr. **RICHARDS** replied: The Government of India have reported that 11 districts out of the 29 in the Punjab are infected, and that the mortality from Jan. 1st to the end of March is estimated at 38,000, including 25,000 deaths in March. Figures for the first two weeks of April have not yet been received, but in the week ending April 19th there were 12,393 deaths. The epidemic is less severe than in 1902, 1904, 1905, 1907, and 1915, but has assumed alarming proportions. The measures taken are chiefly directed towards inoculation and disinfection. Funds have been provided for additional staff in each infected district and for the adequate supply of plague vaccine. A vigorous inoculation campaign has been undertaken and resulted in 30,000 inoculations weekly for a considerable period. The total number of inoculations to April 19th was over 236,000, which is a greater number than in any previous year since 1903. Conditions will favour a decline of the epidemic in the present month. A decline had set in in the Southern Punjab by the middle of April.

Reports on Small-pox Outbreaks.

Mr. **GEORGE OLIVER** asked the Minister of Health whether in cases where notification of an outbreak of small-pox had occurred any special report as to the sanitary conditions of the property or neighbourhood was made to his department.—Mr. **WHEATLEY** replied: No such special reports are made to my department as a matter of routine, but when an outbreak of small-pox is investigated by one of my medical officers he reports as to all the circumstances affecting the outbreak.

TUESDAY, MAY 6TH.

Detention at a Mental Hospital.

Lord **HENRY CAVENDISH-BENTINCK** asked the Secretary of State for War whether he could explain why Lieut. C. H. Clendining, 3rd Battalion Royal Irish Rifles, who was detained as an alleged mental case at the station hospital, Cawnpore, during September 1917, was permitted to retain in his possession a sporting gun, revolver, and ammunition, and to leave the hospital to go out shooting in the jungle; and if he was aware that this officer was placed in hospital without being examined by any medical officer.—Mr. **WALSH** replied: With regard to the first part of the question I have at present no information before me. With regard to the latter part, I understand from Lieut. Clendining's own account that he was ordered to hospital by the senior medical officer after examination. As I informed the hon. Member for Dartford on March 4th last, the Army Council are awaiting the report of the Government of India before investigating the case in accordance with the procedure laid down in Section 42 of the Army Act for dealing with the complaint of any officer who considers himself wronged. I understand that the report in question has just been received by the India Office and is being communicated to the War Office.

River Pollution in Fife.

Mr. DUNCAN MILLAR asked the Secretary for Scotland whether his attention had been drawn to the serious pollution of the river Leven in Fife: and whether, in view of the danger to public health thereby created, he was prepared to take steps to secure the proper treatment of the effluents from factories and works discharging into the river, so as to permit of its purification.—Mr. ADAMSON replied: My attention has been called to the pollution of the river Leven. The initiative in such cases rests with the local authorities, who are empowered with the consent of the Scottish Board of Health to take proceedings against offenders. In the event of a refusal on the part of a local authority to prosecute, any person interested may apply to the Board, who are thereupon required to hold an inquiry and may thereafter direct the local authority to institute proceedings.

Royal Commission on National Insurance.

Sir KINGSLEY WOOD asked the Prime Minister whether the character of the Royal Commission to inquire into national insurance had now been determined; and when the same would be constituted.—Mr. GREENWOOD replied: My right hon. friend regrets that he is not yet in a position to make a statement on the subject referred to by the hon. Member, but will do so as soon as possible.

Pension Final Awards.

Mr. EGAN asked the Minister of Pensions what steps he had taken to meet the serious complaint that, in cases where the final award was set aside on appeal to the pensions (assessment) appeal tribunal, the Ministry took no further action in the case.—Mr. J. W. MUIR replied: My right hon. friend has caused instructions to be issued to the effect that in all cases of this nature the officer or man concerned shall be re-examined, as soon as possible after the decision of the Tribunal, by a medical board with a view to the award of any further compensation which his condition may justify.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, May 13th.

PSYCHIATRY: at 8.30 P.M.
Annual General Meeting:
Election of Officers and Council for 1924–25.
Discussion:
On Proposed Changes in the Law Regarding Criminal Responsibility of the Insane, to be opened by Mr. Donald Carswell.

Wednesday, May 14th.

SURGERY: SUBSECTION OF PROCTOLOGY: at 6 P.M.
Annual General Meeting:
Election of Officers and Council for 1924–25.

Thursday, May 15th.

DERMATOLOGY: at 5 P.M. (Cases at 4 P.M.)
Annual General Meeting:
Election of Officers and Council for 1924–25.
Cases:
Dr. Knowsley Sibley: Case of Disseminated Lupus Erythematosus.
Dr. G. Pernet: Porokeratosis.
Dr. H. Semon: Case of Livedo Annularis (a rare type, with sections).
Other cases will be shown.
Paper:
Dr. Civatte (Paris): Psoriasis (illustrated by microscopic sections).

Friday, May 16th.

ELECTRO-THERAPEUTICS: at 7.30 P.M.
Annual General Meeting:
Election of Officers and Council for 1924–25.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, W.

TUESDAY, May 13th.—5.15 P.M., Prof. Joseph Barcroft: The Effect of Altitude on Man. (Lecture III.)

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, Chandos-street, W. 1.

THURSDAY, May 15th.—8.15 P.M., Prof. Warrington Yorke and Dr. J. W. Scott Macfie: Observations on Malaria made during the Malaria Treatment of General Paralysis. (Preceded, at 7.45 P.M., by a demonstration.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, May 12th, to SATURDAY, May 17th.—CENTRAL LONDON OPHTHALMIC HOSPITAL. Mon., 2 P.M., Mr. Oliver: Plastic Operations on the Eyelids. Tues., 2.30 P.M., Mr. Gibb: Iritis. 4.30 P.M., Mr. Williamson-Noble: Inflammation of the Eye. Pathology. Thurs., 2.30 P.M., Mr. Cunningham: Interstitial Keratitis. Fri., 4.30 P.M., Mr. Neame: Squint.—CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL. Special intensive course.—INFANTS HOSPITAL. Mon., May 12th, to Sat., May 24th. Special Course in Infants' Diseases (for Medical Officers of Welfare Centres and others). 2 P.M. to 5 P.M. daily.—LONDON LOCK HOSPITAL. Clinical work daily. Lectures at Dean-street: Mon., 5 P.M., Mr. Gibbs: Treatment of Syphilis. Tues., 2.30 P.M., Mr. McDonagh: The Theory and Practice of the Treatment of Syphilis. Wed., 5 P.M., Mr. Lindsay Rea: Ophthalmia Neonatorum, its Recognition and Treatment. Thurs., 2.30 P.M., Mr. W. Victor Corbett: Practical Demonstration of Tests Used in Syphilis and Gonorrhœa. Fri., 4 P.M., Mr. Johnston Abraham: Late Sequelæ of Gonorrhœa in the Female.—ST. MARK'S HOSPITAL FOR DISEASES OF THE RECTUM. Operations, clinical demonstrations, and lectures will be in progress during the day.—MAUDSLEY HOSPITAL. Mon., 3.30 and 5.30 P.M., Dr. Bernard Hart: The Psychoneuroses. Tues., 2.30 P.M., Dr. F. C. Shrubsall: The Practical Aspect of Mental Deficiency. 4.30 P.M., Sir Frederick Mott: The Pathology of Mental Diseases. Wed., 2.30 P.M., Dr. E. Mapother: Demonstration in Clinical Psychiatry.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, May 12th.—11 A.M., Surgical Registrar: Surgical Wards. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Dr. Simson: Diseases of Women.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.

WEDNESDAY.—11 A.M., Medical Registrar: Medical Wards. 12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Pernet: Skin Dept.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 12 noon, Dr. Scott Pinchin: Diseases of the Heart. 2 P.M., Mr. MacDonald: Genito-Urinary Dept.

FRIDAY.—10 A.M., Dr. Drummond Robinson: Gynæcological Operations. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Dept.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy Dept. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE. (Prince of Wales's General Hospital, Tottenham.)

(At 4.30 P.M.)

MONDAY, May 12th.—Mr. Aubrey Goodwin: Uterine Hæmorrhage.

TUESDAY.—Dr. J. Metcalfe: The Opaque Meal and its Interpretation.

WEDNESDAY.—Dr. J. Browning Alexander: Dyspepsia.

THURSDAY.—Mr. W. E. Tanner: Tuberculosis of the Mesenteric Glands in Children.

FRIDAY.—Mr. W. Ibbotson: The Essentials in Hearing and Equilibration Tests.

KING'S COLLEGE, Strand, W.C.

THURSDAY, May 15th.—5.30 P.M., Prof. T. H. Brice, F.R.S.: The Development of the Human Embryo (University of London Advanced Lectures in Anatomy).

FRIDAY.—5.30 P.M., Second Lecture.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C.

POST-GRADUATE COURSE.

MONDAY, May 12th.—12 noon, Dr. Greenfield: The Cerebro-spinal Fluid. 2 P.M., Dr. Hinds Howell: Out-patient Clinic. 3.30 P.M., Dr. Kinnier Wilson. Lecture: Temporo-sphenoidal Epilepsy.

TUESDAY, May 13th.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Adie. Lecture: Muscular Atrophies.

THURSDAY, May 15th.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Walshe. Lecture: Clinical Disorders of Muscle Tone.

FRIDAY, May 16th.—2 P.M., Dr. Gordon Holmes: Out-patient Clinic. 3.30 P.M., Mr. Sargent. Lecture: Tumours of Ponto-cerebellar Angle.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.

THURSDAY, May 15th.—5 P.M., Mr. Richard Lake: Hearing Tests. (Geoffrey E. Duveen Lectures in Otology.)

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, May 15th.—4 P.M., Dr. Poynton: Acetonæmia associated with Volvulus of the Small Intestine.

ST. JOHN'S HOSPITAL, Leicester-square, W.C.
TUESDAY, May 13th.—5 P.M., Dr. Adamson: Affections of the Nails.
THURSDAY.—5 P.M., Dr. Griffith: Pemphigus and Bullous Eruptions.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)
MONDAY, May 12th.—(At the Children's Hospital.)
TUESDAY.—(At the Southern Hospital.) Mr. Nuttall: Ulcerative Colitis.
WEDNESDAY.—(At the Northern Hospital.) Mr. Monsarrat: Hæmaturia.
THURSDAY.—(At the Stanley Hospital.) Dr. A. G. Gullan: Encephalitis Lethargica.
FRIDAY.—(At the Royal Infirmary.) Mr. Kennon: Surgical Cases.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.
TUESDAY, May 13th.—4.15 P.M., Dr. J. Wharton: Ophthalmic Cases.

BRISTOL UNIVERSITY POST-GRADUATE DEMONSTRATIONS.
WEDNESDAY, May 14th.—3.30 P.M. (at the Hereford General Hospital), Mr. L. E. Claremont: Care and Treatment of Children's Mouths.

Appointments.

EAST, W. NORWOOD, M.D. Lond., M.R.C.S., L.R.C.P., has been appointed Medical Inspector, H.M. Prisons, England and Wales.

FAILL, C. J. C., F.R.C.P. Edin., L.R.C.S. Edin., L.R.F.P.S. Glasg., Chief Clinical Tuberculosis Officer, Leeds.

NIXON, H. C., M.D. Edin., Physician, Royal Mineral Water Hospital, Bath.

REA, S. P., M.B., B.S. R.U.I., Medical Officer for the Bangor Dispensary District.

WALKER, N., M.B., Ch.B. Manch., Assistant Medical Officer to the Out-patient Department, Royal Manchester Children's Hospital.

Certifying Surgeons under the Factory and Workshop Acts: ROSS, T. S. (Milborne Port District of Somerset); WILSON, J. T., M.B., Ch.B. Edin. (Dronfield); MANWARING-WHITE, R. M., M.D., Ch.B. Edin., F.R.C.S. Edin. (Northwich); and DONALD, H. C., M.B., Ch.M. Glasg. (Bishopton).

Manchester Royal Infirmary: ELLISON, B. L., M.B., Ch.B. Manch., Resident Medical Officer (Central Branch); HOGBEN, F. A., M.R.C.S., L.R.C.P. Lond., Assistant Medical Officer (Central Branch); COOK, B., M.B., Ch.B. Manch., Clinical Assistant; APPLETON, J. H., M.B., Ch.B. Manch., Senior House Surgeon.

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Infirmary.—Hon. Asst. Med. Electrician.

Aden Settlement.—Executive Health Officer. Rs.800 per mensem.

Belfast, Queen's University.—Lectureship in Anatomy.

Bradford Children's Hospital.—H.S. £1000.

Brentwood, Essex High Wood Hospital for Children.—Jun. Asst. M.O. £560.

Brighton, Hove Hospital, Sackville-road, Hove.—R.M.O. £150.

Cardiff, University College of South Wales, &c.—Prof. of Path. and Bact. £1500.

East Sussex County Mental Hospital, Hellingly.—Jun. Asst. M.O. £350.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—H.P., Obstetric Asst., and Two H.S.'s. Each £50. P. for Mechano-Therapeutic Dept.

Gt. Yarmouth Hospital.—H.S. £150.

Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—Radiologist £100.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Hon. Med. O. for X Ray and Electro-Therapeutics.

Hospital of St. John and St. Elizabeth, 40, Grove End-road, N.W.—Asst. Radiologist. £50.

King Edward VII. Sanatorium, Midhurst, Sussex.—Med. Sup. £1000.

Leicester Royal Infirmary.—Hon. P. and Asst. Hon. P.

Liverpool Hospital for Consumption and Dis. of Chest, Mount Pleasant.—Asst. M.O. and Pathologist. £150.

Liverpool, Royal Southern Hospital.—Hon. Gynæcologist and Hon. Asst. Orthop. S.

Liverpool, Walton Institution.—Res. Asst. M.O. £200.

London County Council Education Officers' Dept.—Woman Organiser of Physical Education. £696.

Loughborough and District General Hospital and Dispensary, 9, Leicester-road.—Res. H.S. £175.

Manchester, Ancoats Hospital.—H.S. £100.

Manchester Royal Eye Hospital.—H.S. Senior £150. Junior £120.

Margate, Princess Mary's Hospital for Children, Cliftonville.—Second A.M.O. £560.

Middlesex Hospital Medical School, W.—Two Cancer Research Scholarships. Each £150.

Middleton-in-Wharfedale, Sanatorium.—Asst. M.O. £500.

Miller General Hospital for South-East London, Greenwich-road, S.E.—H.S. £125.

Mines Dept., Dean Stanley-street, Millbank, S.W.—Temp. Medical Inspector. £1000.

National Hospital for the Paralysed and Epileptic, Queen-square, W.C.—Registrar. £200.

Newcastle-upon-Tyne, University of Durham College of Medicine.—Vacancy in Dept. of Bacteriology. £600.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Cas. H.S. £100.

Queen Mary's Hospital for the East End, Stratford, E.—Hon. Asst. P.

Royal College of Surgeons of England.—Hunterian Professor and Arris and Gale Lecturer.

St. Giles Hospital, Camberwell, S.E.—Radiologist. £110.

Sheffield, Jessop Hospital for Women.—Hon. Physiologist. Hon. Asst. S. Also Asst. H.S. for Gynæcological and Maternity Depts. £100.

Sheffield Royal Hospital.—Cas. O. £150. Supt. and Secy.

Sheffield Royal Infirmary.—H.P. £60.

Union of South Africa Government Mental Hospital Service.—A.P.'s. £460.

Warrington County Borough.—Asst. M.O.H. £450.

West End Hospital for Nervous Diseases, Welbeck-street, W.—Half-time Pathologist. Also Locum Tenens for same post. Each £300. Also Radiologist.

West London Hospital, Hammersmith-road, W.—Med. Reg. £100.

Western Dispensary, 38, Rochester-row, Westminster, S.W.—Vacancy on Attending Medical Staff.

Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointment: Pickering, Yorks (North Riding).

Births, Marriages, and Deaths.

BIRTHS.

ATKIN.—On April 27th, at Fulwood-road, Sheffield, the wife of C. S. Atkin, M.B., of a son.

MARRIAGES.

COLBORNE—CUTBUSH.—On April 30th, at the Parish Church, Headcorn, Surgeon Lieutenant-Commander William John Colborne, R.N., to Florence Alice, youngest daughter of Mr. and Mrs. W. Cutbush, of Headcorn, Kent.

FAWDRY—MEARNS FRASER.—On April 29th, at Portsmouth Parish Church, John Wood Fawdry, *M.C.* (Captain, Royal Warwickshire Regiment), second son of the late A. G. Fawdry, Esq., and Mrs. Fawdry, Edgbaston, to Lois Mearns, younger daughter of Dr. and Mrs. A. Mearns Fraser, Southsea.

HICKS—ELLIS.—On April 22nd, at St. Mary Magdalene Church, Norwich, Ernest Wm. Hicks, M.R.C.S., L.R.C.P., to Cecilia Mary Susan, daughter of Rev. A. H. and Mrs. Ellis.

JOLL—WINSLOE.—On April 30th, at St. Mark's, North Audley-street, by the Rev. W. E. Pennyman, M.A., Cecil Augustus Joll, M.S. Lond., F.R.C.S. Eng., to Laura Merriall Winsloe.

SWAINE—PEGRUME.—On April 26th, at All Souls', Langham-place, Dr. Richard O. Swaine, of Christchurch, Hants, to Nancy Hillyard, youngest daughter of the late J. Pegrume and Mrs. Pegrume.

DEATHS.

GRAHAM.—On April 29th, at "Shoreside," Bolton-le-Sands, Dr. Charles Robert Graham, aged 67.

SPENCER.—On April 24th, at Tavistock, Devon, Dr. Edward Macready Spencer, of Cardiff, aged 58 years.

WYLIE.—On May 2nd, at Leicester, Angus Wyllie, M.A., M.B. Camb., of The Ropewalk, Nottingham.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

THE LANCET: SUBSCRIPTION RATES.

INLAND	One Year	£2	2	0
	Six Months	1	1	0
	Three Months	0	10	6
ABROAD	One Year	2	10	0
	Six Months	1	5	0
	Three Months	0	12	6

Subscriptions not paid in advance are charged out at the published price of 1*s.* per copy, plus postage. Cheques and P.O.'s (crossed "Westminster Bank, Ltd., Covent Garden Branch") should be made payable to THE MANAGER, THE LANCET Offices, 423, Strand, London, W.C. 2.

For complete scale of advertisement charges apply to the Manager.

Notes, Comments, and Abstracts.

DIED IN HARNESS.

A STUDY OF THE SURGEONS' ROLL.

By Victor G. Plarr,

LIBRARIAN AND COMPILER OF THE ROLL OF FELLOWS, ROYAL COLLEGE OF SURGEONS OF ENGLAND.

The recent death at a comparatively early age of Sir Archibald Reid adds another name to the roll of martyrs to science. He had devoted himself to roentgenology and ultimately was the victim of the methods he had improved. But though science thus counts a number of martyrs in its ranks, duty, or mere professional routine, counts many more. On examining the lives of some 2000 or more medical men, Fellows of the Royal College of Surgeons, many of them general practitioners, we can count during a period of 80 years nearly as many men who may be said to have qualified as martyrs to the day's work. As long ago as 1847 John Phillips Potter, F.R.C.S., when assistant to the famous Liston, punctured a knuckle when taking a diseased hip-joint from a subject for dissection, and after acute suffering, heroically borne, died within three weeks of his accident and only five weeks of his appointment to the assistant surgeoncy of University College Hospital. He was a man of general culture and rare promise. Deaths due to operation wounds—punctures and cuts—or to infections have continued to occur even after the introduction of rubber gloves. Thus, taking the names in alphabetical order, we find that Dr. Andrew Clark died in 1913 of a bad cut received during one of his operations seven years earlier; Campbell Dykes died a victim to septicæmia, contracted while operating in October, 1911; Dr. Webb Jones accidentally inoculated himself when giving an intravenous injection to a colleague dying of typhus during the epidemic of that disease in Alexandria early in 1917. Operation infection also caused the death of Mr. Charles Killick, M.A. Camb., F.R.C.S., Dr. Henry Percy Potter, of Kensington, in 1917—a most pathetic case—and Dr. Arthur John Sharp, of Nottingham, in 1910. In some of these cases the hands may not have been properly gloved. None the less, these gentlemen were martyrs to duty, and to their goodly company might be added a list capable of indefinite extension of those who overworked themselves during many years, insisted on visiting patients when themselves very ill, or, in the recent war period, did the work of colleagues at the Front when themselves past work. Here it would be invidious to name names.

A curious list might be made of those who succumbed to their specialties, the diseases in which they were interested. Thus, in 1906, Kendall, of Bristol, died of an appendicitis operation after operating on a child whose appendix he removed. In 1889 Dr. David Reid McKinnon died combating a yellow fever epidemic, in which he had taken great interest, in British Honduras. John Henry Farbstein, resident medical officer of the Hull Workhouse, died of phthisis in 1911, having spent much time in the study of the disease in the consumption ward, and in 1888 Francis Stanhope Hawkins, an old Tonbridge School and Oxford man, died of diphtheria after clearing the tube in the throat of a child, presumably by the primitive method of suction. The case of that veteran friend of English surgery, Just Lucas-Championnière, may here be included. He died in 1913 of cerebral hæmorrhage while reading a paper at the Institut on ancient trephining and cerebral localisation. Sometimes a medical man is destroyed of malice prepense by an insane patient. Thus, to cite one instance of several, Samuel Pozzi, the great French gynæcologist, was shot dead in June, 1918, by a discontented melancholic patient on whom he had rightly refused to operate again. Another well-known case of a physician assasinated by a lunatic occurred in Australia not many years ago. With the foregoing instances we might rank those of the medical missionaries who fell victims to the diseases they were endeavouring to stamp out among their semi-civilised and unhealthy flocks. Among these the Chinese missionaries rank high. Dr. James Glenny Gibb, organiser of the Central Red Cross Society's work in the Chinese Revolution of the year 1912, died in the midst of his labours; Cecil Frederick Robertson, M.B., F.R.C.S., died of illness contracted among his out-patients in 1913; and, at about the same time, Dr. Herbert Stanley Jenkins, overwhelmed with work in the Sianfu (Shansi) Hospital, succumbed to fever. He was in his thirty-ninth year, and so great was the stress of duty unavoidably imposed upon him in the new mission hospital that he saw as many as 60 out-patients the day before he died. Out-of-the-way cases of death at the post of duty, not referable to any of the above categories, occur in the older medical biographies. Charles Aston Key, famous as an operator and pioneer anæsthetist, died greatly interested in his own case. His death from cholera, from which he only suffered for a few hours, occurred in 1849, during a historic epidemic in the City, and is minutely described, step by step, by his medical attendant, neither he nor Key having the slightest suspicion of the water-borne nature of the disease. It is a memorable document. In 1863 Charles Allen Chavasse, F.R.C.S., died in the very act of attending a patient in his surgery; Henry Work Dodd, F.R.C.S., met a similar fate in his consulting room in 1921; but perhaps the most remarkable tragedy occurred when an old surgeon of the past died at the very moment of delivering a mother of her child.

POISON GAS IN NAVAL WARFARE.

Poison gas is not usually associated with naval warfare, but that it has been so used is stated by Lieut. Paul W. Hains, of the Construction Corps, U.S.N., in a recent number of the *Naval Bulletin* of the U.S. Naval Medical Department. In a paper dealing with the protection of capital ships against poison gas, he instances the case of H.M.S. *Botha*, a flotilla leader, which in 1917 passed through a smoke screen into which the Germans had mixed poison gas. The ship was exposed for only about a minute, but "every man on her was thrown into paroxysms of nausea and suffered a most violent headache." The author wonders what would have happened if the Turks had discharged poison gas over and about the fleet lying off the Dardanelles. To prevent a ship being thus put out of action, protection of some kind must be given to the personnel, and the writer requires that every man shall have a mask, the effective filter being arranged on top of his head so as not to hamper his arm work, but an "optical" mask must be attached to sighting instruments, so that the gun-layer, for example, shall use his mask habitually at his work, and become thoroughly accustomed to it. Each man must also have a suit of protective clothing, suitably impregnated, to neutralise vesicants like mustard gas. The wearing of such equipment materially reduces efficiency and output of work, as the writer tells us he found when, wearing a gas mask, he tried to play baseball; he had even difficulty then in merely writing. As the sailor in action is called upon for the very hardest work of his life, some other method of protection must be sought; protection must be given to the air of the ship, not to the individual. Lieut. Hains thinks the best method will be to maintain a positive air pressure continuously within the ship by over-ventilation. Then offensive air from the outside cannot drift in; a good scheme, but we are not told whence is to come the uncontaminated air needed to keep up the pressure. However, the turrets are to be freed from hurtful gases by the "Seco" spray, which washes air, eliminating 95 per cent. of poisonous gases, and the conning tower and a reconstructed engine-room are to have a system of continuous purification by soda-lime, as used in submarines, removing carbonic acid and moisture, and oxygen is to be gradually added from cylinders. All these proposals mean increased weight to be carried by the ship, and so make her a little less effective; but the gas menace is urgent.

THE ROCKEFELLER FOUNDATION.

A review of the activities of the Rockefeller Foundation in 1923, written by George E. Vincent, its President, will shortly appear. Meanwhile, the Information Service of the Rockefeller Foundation has provided in a single breathless sentence a summary of the activities of the Foundation during the past year, which are amazing in their scope and generosity.

During the year 1923 the International Health Board, the China Medical Board, and the Division of Medical Education of the Rockefeller Foundation supplied Fellowship funds for 636 individuals in 29 different countries; supported through the League of Nations interchange institutes for 54 public health officers from 27 nations; arranged international visits of one commission and of 24 visiting professors; furnished emergency relief in the form of medical literature or laboratory equipment and supplies to institutions in 15 European countries; sent scientific material to Japan after the earthquake and invited a group of Japanese medical scientists to use the laboratories of the Peking Union Medical College as guests of the institution; continued to contribute to schools or institutes of hygiene at Harvard, London, Prague, Warsaw, and São Paulo, Brazil; coöperated in nurse training at Yale University and in France, Belgium, Brazil, China, and the Philippines; accepted an invitation from Brazil to participate in a comprehensive attack upon yellow fever; had a share in demonstrations of malaria control in 12 American States, and conducted malaria surveys or studies in the United States, Brazil, Australia, Nicaragua, Porto Rico, Salvador, the Philippine Islands, and Palestine; either continued or began anti-hookworm work in conjunction with 20 Governments in various parts of the world; contributed to 183 county health organisations in the United States, New Brunswick (Canada), and Brazil; continued a study of the medical schools of the world by visits to Belgium, Austria, Czecho-Slovakia, Germany, Hungary, Poland, Turkey, Hong-Kong, the Straits Settlements, Siam, Canada, England, Scotland, Wales, the Netherlands, Mexico, and Colombia; offered to contribute £280,750 sterling to the development of medical education in certain universities in the British Isles; gave $500,000 to the University of Alberta, and pledged $250,000 to the University of Pennsylvania toward buildings for anatomy and physiological chemistry; continued to support a modern medical school and teaching hospital in Peking; aided two other medical schools and 25 hospitals in China; assisted pre-medical education in several institutions in China and agreed to do this also in Bangkok, Siam; lent representatives to Governments and institutions for various types of counsel and service; continued to support a disease reporting service of the Health Section of the League of Nations; contributed to mental hygiene projects, demonstrations in dispensary administration, organisation of dispensary work in France, and to other undertakings in the fields of public health and medical education.

Expenditure in 1923.

The following table presents a summary of the expenditure in various fields during 1923:—

Public Health.	
International Health Board—hookworm disease, malaria, yellow fever, county health work, laboratory service, Fellowships, &c.	$2,332,511
Mental hygiene	52,153
Hospital, dispensary, and nursing studies	161,504
School of Public Health, Harvard University ..	618,750
National Health Council	9,350
Medical Education.	
China Medical Board	1,354,942
Canadian Medical Programme	1,596,592
London Medical Centre	621,472
University of Chicago	1,046,952
Columbia University	8,333
Central Europe—journals and apparatus	60,316
Pasteur Institute	20,000
Fellowships, studies, &c.	202,403
Miscellaneous.	
Concluding payments on ten-year pledges to educational enterprises	37,500
Concilium Bibliographicum, Zürich	20,000
Fellowships in physics, chemistry, and the biological sciences	97,428
National Information Bureau	1,000
Administration.	
Executive offices	189,869
Total	$8,431,075

The record requires little comment. Those who have experience of the care taken by this giant organisation to investigate the claims made upon its benevolence know that the percentage of wasted money or effort is reduced to a minimum, while no reasonable scheme for developing research or education or promoting health in any part of the world is refused consideration.

COLONIAL HEALTH REPORTS.

Bahamas.

THE estimated population on Jan. 1st, 1923, was 56,924. The birth-rate in 1922 was 31 per 1000 and the death-rate 25·2 per 1000. The Bahamas General Hospital (originally established in 1809 as a poor-house) comprises the hospital proper, a paying patients' ward, infirmary, dispensary, lunatic asylum, and leper wards. The number of inmates on Dec. 31st was: Alexandra Hospital, 76; Victoria Jubilee Infirmary, 37; lunatic asylum, 46; leper asylum, 8. During the year there had been 955 admissions, making a total under treatment of 1105. There were 148 surgical operations performed under a general anæsthetic in the Alexandra Hospital; 4252 cases were prescribed for or treated for minor surgical ailments at the out-patients' (or dispensary) department. At the public dispensary 17,324 prescriptions were dispensed.

St. Vincent.

The population of this colony was estimated by the Registrar-General on Dec. 31st, 1922, to be 46,220. In 1922 the birth-rate was 36·37 and the death-rate 21·31 per 1000. Of the total number of births 71·1 per cent. were illegitimate. The general health was good. There was a mild epidemic of measles, and infantile diarrhœa continued to be prevalent. The campaign against yaws by intramuscular injection of novarsenobillon was pressed vigorously with very satisfactory results. During the year 4604 cases—over 10 per cent. of the population—were treated and of these over 78 per cent. were returned as cured. The temperature throughout the year varied from 76·20° to 80·8° F. The total rainfall for the year was 79·74 inches.

PROPOSED VISIT OF SPANISH MEDICAL MEN TO THE BRITISH EMPIRE EXHIBITION.

To the Editor of THE LANCET.

SIR,—On the occasion of the celebration of the great British Empire Exhibition it is our desire to organise a mission of Spanish University professors and medical and scientific men with a view to making a visit to this exhibition. At the same time we should like to avail ourselves of the opportunity to hold conferences, discuss scientific affairs, and visit the institutions, hospitals, and so forth in the United Kingdom, and thus help to tighten the bonds already uniting the men of science of Great Britain with their brothers of the Iberian Peninsula. In order, however, to organise such an expedition in a fitting manner it is essential that we should have the support and assistance of our British colleagues.

I am, Sir, yours faithfully,

DOCTOR CARLES,
Editor, Laboratorio, Revista de Ciencias Biológicas y de Medicina Experimental, Pelayo 24, Barcelona.

April 30th, 1924.

THE NURSE'S INTEREST IN HER WORK.

To the Editor of THE LANCET.

SIR,—At least one institution for hospital nurses for private cases advertises the fact that its nurses return at intervals to the wards of the hospital between their private cases, and I should like, if I may, to call attention to the extreme importance of this, not only for keeping the nurses' training fresh and up to date, but also for the general good of everyone concerned. Efficient nurses who are keen at their work must inevitably find many private cases, with their usually prolonged periods of convalescence, dull and uninteresting, and it is well known that private nurses often long for the variety and constant urgency which is only obtainable in a hospital ward, and usually the better the nurse the more frequently this feeling occurs. If it were the universal custom for private nurses to return for fixed periods to the wards of a hospital they would not only keep their knowledge fresh, but the comparative monotony of many private cases would be a relief and not merely a period of dull inactivity. Such matters of applied psychology are far more important than they appear.

I am, Sir, yours faithfully,

May 4th, 1924. CYRIL BRUYN ANDREWS.

SEAMLESS BIAS BANDAGES.

THESE bandages are made of a muslin-like fabric, soft in texture, and cut "on the cross." The elasticity of the fabric allows it to conform to the contour of the limbs or body and there is little or no chance of the bandage slipping out of place, while, in tension, the threads of which it is composed are drawn closer together. Where a thin and porous bandage with firm pressure is required this invention should prove useful. The makers are the Seamless Bias Manufacturing Company, of Newark, N.J., and the European agent Mr. A. H. E. Bercham, M.I.M.E., 3, Casewick-road, West Norwood, London, S.E. 27.

MALARIA SIMULATING THE "ACUTE ABDOMEN."

THAT chameleon, malaria, furnishes many difficulties of diagnosis to practitioners in hot countries. It may, e.g., simulate cholera or dysentery (THE LANCET, 1920, ii., 1334). Another remarkable case is described in the *Arch. f. Schiffs- u. Tropen-Hygiene* (vol. xxviii., 2) by Dr. O. Urchs, whom it nearly misled. He was taking medical charge of miners at Moengo, in Dutch Guiana, when he was called out one night to see a young Japanese, usually in good health except for attacks of fever, but now suddenly taken ill with rigors (temp. 103° F.), severe shock, and extreme pain in the belly; he was a picture of misery, groaning all the time, both hands always pressed against the abdomen. The belly was hard as a board, any movement increased the pain, which seemed to be at its worst 2½ inches below the right costal margin. Patient was constipated and had been vomiting, so it appeared that a laparotomy might be necessary. But when better lighting was obtained, there showed up, in spite of the tension of the abdominal wall, a swelling filling the left hypochondrium, and extending to the navel, painful, and most particularly tender along its edge. This was recognised as an acute malarial swelling of the spleen, which causes great pain by the sudden stretching of capsule, mesentery, and ligaments. With injection of 15 gr. of quinine, cold compresses, and the like, the pain ceased during the night, and next day urobilin was found in the urine, tertian parasites in the blood, and the blood picture proved this attack to have been a relapse.

Arris and Gale Lecture

ON THE

MECHANISM OF THE LARYNX.

Delivered before the Royal College of Surgeons
of England on April 28th, 1924,

By V. E. NEGUS, M.B., B.S. Lond., F.R.C.S. Eng.,
CLINICAL ASSISTANT, THROAT AND EAR DEPARTMENTS, KING'S COLLEGE HOSPITAL.

An impression is gained from the literature that the larynx is the organ of voice, and that it has been evolved to subserve this function. I suggest that this view is erroneous, and that its use for purposes of voice is only a subsidiary one of several functions. In examining the larynx in various types of animals one is impressed by the fact that there is no marked relation between the structure of the organ and the vocal powers of its possessor. Vocal cords similar to those of man are to be seen in many animals which are naturally silent, as in most bears, whilst there is a complete absence of vocal cords as we usually picture them in many habitually noisy species such as the domestic cow. Many instances might be given, but the point needs a special study of its own.

To investigate the functions and mechanism of the larynx we must approach the subject with an open mind, and trace the evolution of the organ from its most primitive beginnings; later on we can examine each secondary modification as it appears, and see what relation it has to the habits of the individual, without blurring our perception by concentrating attention solely on the habit of phonation.

Evolution of the Larynx.

In the dipnoi, or lung fish, there is a mechanism developed to ensure survival of the individual when the water of the river in which it lives has dried up. This mechanism takes the form of lungs, morphologically comparable to those of mammals. The pulmonary outgrowth springs from the ventral wall of the fore-gut, and at its orifice a sphincteric band of muscle is developed to keep it closed at all times except when air is passing through; food and water are thereby prevented from entering. A primitive larynx thus comes into existence, with the primitive function of closing the air tract.

To compare this process of the evolution of a simple larynx (Fig. I.) with what occurs in human embryology, we derive information from the work of Prof. J. E. S. Frazer in particular. The pulmonary outgrowth appears in the floor of the fore-gut in the third week; the actual boundaries of the primitive sagittal fissure are derived from the sixth visceral arches. At first the fissure lies flat in the pharyngeal floor, just as it does in the lung fish, but the further processes of development carry it beyond this simple stage, and it is found that at no time is there merely a sphincteric band of muscle present to close its orifice; for many modifications creep in in relation to varied functions that must be carried out, each one of which will be studied in its correct place.

Origin of Arytenoid Cartilages.—As air is forced into the lungs by contractions of the pharynx in Dipnoi, and as the call for air is slight, passive dilatation of the glottis is all that is required; but as the demand for air increases, so some mechanism for active opening has to be evolved. This mechanism is seen in the form of simple dilator muscle fibres in Protopterus, one of the Dipnoi. But these simple fibres are not so efficient as the dilator fibres of the iris of the eye, for instance, and so we find that in Sirens and Axolotl a lateral cartilage has made its appearance on either side of the trachea, and to its pointed extremity the dilator fibres gain attachment. These cartilages serve to maintain patency of the air tube, and in some Salamanders and all higher forms the tips are separated off by muscle action, and appear as arytenoid cartilages, whilst the lower parts fuse together and form a primitive cricoid ring. The primary function of the arytenoids is for opening, and not for closing the glottis, for the latter action can be done efficiently by the sphincteric muscle. In the human embryo the margins of the glottis, made up of the sixth arches, are found to grow rapidly, and become known as the lateral masses. By a condensation of mesenchyme cells in them there appear the nuclei of the arytenoid and cricoid cartilages; the latter arises in two centres, which subsequently coalesce, in just the same way as the previously separated lateral plates are seen to fuse in animals above the level of Axolotl. At no time, however, are the arytenoid and cricoid cartilages continuous, although they arise from contiguous collections of cells.

Thyroid Cartilage.—In the ventral ends of one or more pairs of visceral arches are developed cartilaginous elements, which will form the thyroid cartilage; in some low forms, such as Echidna, these bars are fused both to the hyoid system and to the cricoid, and help to complete the scaffolding of the larynx.

In the human being the thyroid cartilage is developed in the ventral end of the fourth arch only; only at an early time is it fused either to the hyoid or cricoid elements. Both dilator and sphincteric muscles gain attachments to the cricoid. The sphincter muscle also takes origin from the thyroid element; its continuity at its ventral extremity then becomes interrupted, so that it takes the form of a horse-shoe instead of that of a complete circle.

In such low types as the Alligator the sphincteric muscle wraps round, but is not inserted into the arytenoid, but in higher forms it gains attachment to the cartilage at what becomes the muscular process. The muscle is thus split into five elements—namely, thyro-arytenoideus and crico-arytenoideus lateralis on either side, and inter-arytenoideus in the position of the posterior or dorsal commissure.

Thyro-Arytenoid Fold.—The primitive lateral cartilage is very long, but does not extend quite to the cephalic end of the margins of the glottis, and the forward portion of the boundary of the fissure remains as a membranous fold; this represents the thyro-arytenoid fold, and it is of vital importance, in that it is capable of allowing separation of the tips of the lateral or arytenoid cartilages by virtue of its elasticity. In the human embryo the formation of the thyro-arytenoid fold is complicated by the early formation of a ventricle at the end of the second month; the process can be traced, however, as a condensation of cells in the mesenchyme of the lateral mass, resulting in the formation of what is known as the chordal nodule. Strands of cells run from the latter to the thyroid, cricoid, and arytenoid cartilages, and by stretching out of this tissue between the thyroid and arytenoid there is developed that part of the thyro-arytenoid fold which is known as the vocal cord.

The Definitive Larynx.—In its simple form the larynx consists of cricoid, thyroid, and arytenoid cartilages, and thyro-arytenoid folds, with sphincteric and dilator muscles of varying degrees of complexity; as such it is seen in most reptiles and birds. There are no epiglottis or ary-epiglottic folds, and no separation of thyro-arytenoid fold into true cords and ventricular bands. In endeavouring to discover what part of the complicated human larynx represents the primitive organ as we have thus described it, we rely on the observations of Prof. Frazer. He states that a line drawn back along the true cord, and then upwards along the border of the arytenoid eminence to the inter-arytenoid notch, corresponds with the margin of the original sagittal opening in the pharyngeal floor; this part represents roughly the simple larynx as we have described it. All the parts above this line, such as the ary-epiglottic folds, the cartilages of Wrisberg and Santorini, the major part of the epiglottis, and the ventricular bands, are derived from the general pharyngeal cavity, and not from the pulmonary outgrowth. They are modifications designed to subserve functions we have yet to study, and are parts superadded to the primitive organ; furthermore, by their appearance, the original function of the margins of the glottis, which is to act as a valve for the protection of the air tract against entrance of substances other than air, has been relegated to more recently added structures.

Modification in Shape of Primitive Glottis.—For the efficient carrying out of its primary function of preventing the entrance of food and water into the pulmonary apparatus, it is interesting to notice a change in the shape of part of the simple larynx, which appears in amphibians, reptiles, and birds, and is repeated in the case of many mammals. The configuration is found to be such that the margins of the glottis, when in apposition, present a surface which is convex and dome-shaped above, and concave and vaulted below. The margins of the glottis—made up of the arytenoid cartilages and thyro-arytenoid folds—take on this shape because it is necessary that they should be able to withstand a considerable pressure of water present in the pharynx, and to prevent its entrance into the lungs. At the same time it is not desirable that they should obstruct the exit of air from the trachea.

As a result of this peculiar shape, when the pressure of water—and incidentally that of air—becomes increased on the pharyngeal surface of this laryngeal valve, the margins are the more firmly pressed together. As a consequence, there is relegated to the sphincteric muscle the simple rôle of bringing the margins into apposition, after which closure is more or less automatically maintained; as the pressure rises, so the coaptation of the margins becomes more intimate. When it is desired, however, that air should enter the trachea, the dome-shaped glottic margins must be separated by abductor muscle action, and in consequence the latter muscles attain a greatly enhanced importance in this valvular type of larynx, in comparison to that which they possess in the more simple organ of Protopterus.

FIG. I.

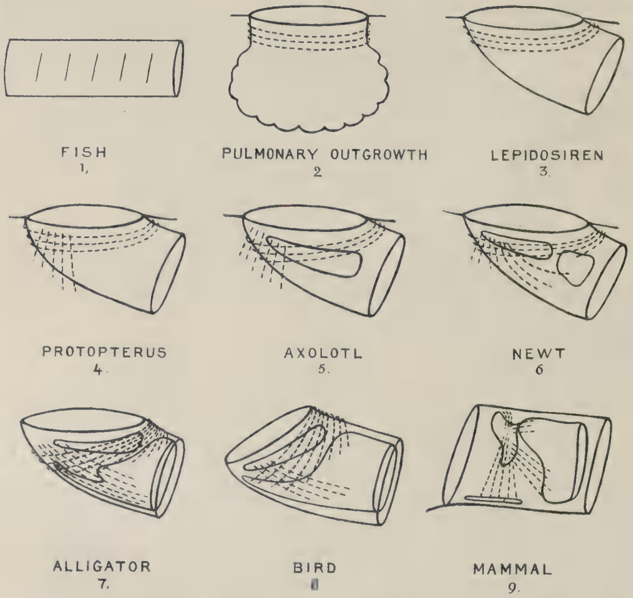

Diagram illustrating the evolution of the larynx.

The dome-shaped modification of the larynx thus confers a mechanical advantage as long as the abductor muscles are efficient, but at the same time it leads to the danger of prevention of entrance of air into the lungs if the dilator mechanism breaks down.

We conclude, then, that the simple type of larynx so far described is a valve designed to guard the entrance of the pulmonary air tract against the entrance of substances other than air; it is modified so as to be able to open actively while respiration is proceeding. The many other functions it takes on, such as those subserving olfaction, circulation, phonation, and so on, are thrust upon it in higher forms, but are not those for which it was developed in the more lowly types of animals.

MODIFICATIONS FOR PURPOSES OF OLFACTION.

Mr. R. H. Burne has given a comprehensive description of the olfactory organ of teleostean fishes (Fig. II.), and has described the mechanism by which water is made to circulate over the olfactory rosette. There is found to be no communication of this simple nose with the food tract in the majority of fish; in Dipnoi, however, such a communication exists. In these fishes inspiration is effected by the swallowing of air through the mouth, as occurs also in some Salamanders and Newts. While the air-breathing proceeded there would therefore be no circulation of air through the nose, and the olfactory sense would not be acute; therefore a communication, or choana, is present in the roof of the mouth, whereby air can be made to pass over the olfactory rosette, so as to give off sufficient odour for perception of scent. There is no necessity for air to pass through the nose, as far as respiration is concerned, in these cold-blooded animals.

In reptiles the mouth does not have to be kept open for chewing, and there are various mechanisms to ensure nasal breathing; in mammals which rely on the olfactory sense to warn them of enemies and poisonous foodstuffs, some mechanism has to be provided to ensure that a current of air shall pass through the nose while the animal is eating with its mouth open.

Primitive Function of Epiglottis.—The epiglottis has this function of shutting off the air tract from the mouth, in association with the soft palate; its primitive function, therefore, is one of olfaction, although it has subsequently taken on other duties. Man has not a keen olfactory sense and his epiglottis is somewhat degenerated; similarly we can see that in microsmatic animals such as Sea Lions, some Cetaceans, and Monkeys, the epiglottis is comparatively small, whilst in the macrosmatic Dogs, Cats, Deer, and so on, it is big and efficient.

In the human fœtus the pulmonary outgrowth appears at about the fifteenth day, and the olfactory pit at the twenty-first. The bucco-nasal membrane breaks down at about the thirty-fifth, and the palate is only completed by about the forty-ninth day. These facts illustrate the probable sequence of events in the evolution of nasal breathing, and indicate that the latter is a secondary modification of respiration.

MODIFICATIONS FOR PURPOSES OF RESPIRATION.

In a Lizard the choana opens on the roof of the pharynx at a right angle, and the glottis opens from the floor of the pharynx in such a way that the air stream has to turn at two more right angles, one from pharynx into larynx, and a second one from the latter into the trachea. Furthermore, there is a wide interval between the choana and the glottis.

Straightening of Air Tract.—There can be traced various stages in which these bends in the air tract have been straightened out, and a good example is seen in many deer and antelopes. (Fig. III.) In them the nostril opens in the axis in which the head is held when running; the nose is wide and straight; the naso-pharynx, with the help of the soft palate, is wide, straight, and extremely long, and opens at the level of the larynx. The latter is brought into apposition with the nasal tube by means of the pharyngeal walls behind and at the sides, whilst in front the passage is made continuous by means of the epiglottis and soft palate; the former lies above the soft palate in the intra-narial position. The aperture of the glottis is tilted, and is at right angles to the axis of the pharynx, and does not lie flat in the pharyngeal floor as it does in most reptiles; consequently there is now no angle between the larynx and the trachea. Air is enabled to pass practically in a straight line from nostril to lung.

Air Tract in Man.—In man the needs of respiration are not so great, and the air tract is not so straight. The anterior nostril opens at right angles to the long axis of the head, and the nasal passage is tortuous; the soft palate is short and the epiglottis is small, so that the larynx is never intra-narial, not even, as far as I have been able to discover, in the fœtus examined in situ in the uterus. (Fig. IV.)

FIG. II.

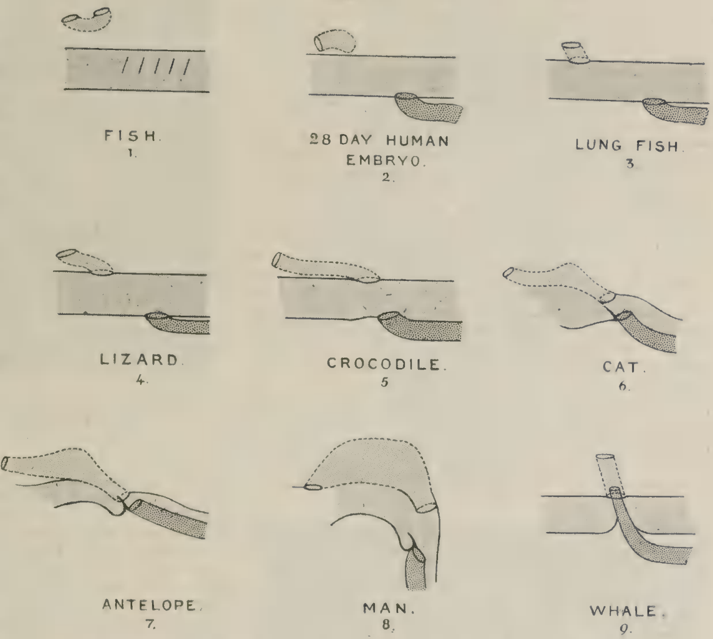

Diagram illustrating modification of larynx in relation to olfaction.
Darkest stippling = pulmonary air tract. Lightest stippling = food tract.
Medium stippling = nasal passage.

The axis of the glottis is in line with that of the trachea, and the mechanism of this change of inclination comes about in early fœtal life through overgrowth of the lateral masses, as compared with that of the central mass, which is a formation lying between the ventral ends of the third and fourth arches. The whole larynx of man drops in the neck from early fœtal life onwards because of four reasons. First, there is no necessity for its apposition to the nasal tube for purposes of olfaction or respiration; second, there is a big tongue in a short muzzle; third, because of changes in the vertebro-basal and pituitary angles as compared with lower types; and fourth, because of downward growth of the face.

In the child mouth-breathing is difficult because of lack of habit and the marked development of the tongue for purposes of suckling; in the adult it is frequently resorted to, although with detriment, because of deficient warming of the air.

Length of Arytenoids.—We have already seen that arytenoid cartilages were evolved in order to open the glottis during the passage of air. In most reptiles the cartilages are very long, but in the higher mammals and in man there are many variations in length, the reason for which must be sought for. As the aperture of the glottis lies flat, or at most only slightly tilted, in the pharyngeal floor of most Fishes, Amphibians, Reptiles, and Birds, so it is possible for the cross-section of the air-way to be increased to an indefinite extent by simple lengthening of the fissure. The glottis when open in these animals is of a triangular shape, the sides very long, and the base very short, and if the sides are long enough, a very big sectional area will be available for the passage of air.

In the case of those animals, however, which have a larynx in which the aperture of the glottis is tilted to a degree approaching a right angle—a modification for diminishing friction of air—indefinite lengthening of the margins of the glottis is impossible, because a laryngeal aperture of this type would not allow deglutition to proceed, if placed transversely in the pharynx. Therefore the glottis is found to be less slit-like in mammals, and to approach more nearly to a broad and short shape when open.

The optimum length for the arytenoids by mathematical calculation is approximately seven-tenths of the diameter of the larynx; at this length the greatest possible sectional area is obtained for the passage of air, and any variation either above or below seven-tenths decreases the available air-way. The extremely fast-running Persian gazelle shows a length of arytenoid 6·9, as compared to a laryngeal diameter of 10; this is very near the optimum, and gives a sectional area which we shall call 49.

Man has need of long valvular thyro-arytenoid folds, otherwise known as vocal cords; consequently he could not have long arytenoids unless his larynx were greatly increased in size, and he is limited in pace thereby. In his case the length is as 4·5 and the sectional area 39. A sloth is still worse off, and has a length of 3·6 and an area of 29. These calculations only show the relative degree to which the larynx can open in each case, and do not give the actual area available for the passage of air, because we have not taken into account the size of the larynx. If we compare the actual cross-section available for air when the glottis is widely open, we find these facts in the case of a man and a horse; the former has a speed compared to the latter roughly as 1 : 2·4, whilst the ratio of the available air-way for each pound of body-weight is approximately 1 : 2·3.

This does not show exactly how much air can pass in either case, but it shows that a man has a poor provision for rapid oxygenation of his tissues in comparison with a fast-running quadruped; so it is evident that in spite of a body otherwise well designed for running, the human individual is at a disadvantage because of the choke at the narrowest part of his air-way—namely, the glottis.

Variations in Size of Larynx.—In some fast-running animals, such as wolves and dogs, there are long and well-formed vocal cords, while the arytenoid cartilages are not so long in comparison to the diameter of the larynx as they are in the case of antelopes. This would produce choking at the glottis were it not for the fact that the larynx itself is very big in comparison to the size of the trachea; the aperture of the glottis is thus large and allows the passage of a volume of air sufficient to carry on respiratory exchange at the high level demanded by the rapid metabolic rate of the animal.

Accessory Aids to Respiration.—It is possible that the laryngeal saccule in man represents a degenerate relic of a mechanism for helping in respiration, by means of which partly used air can be expelled from the lungs, mixed, and forced in again to yield up more oxygen. The saccule appears to me to correspond morphologically and functionally to the air sacs of the higher Apes, and functionally to those of some Seals and Frogs, but the subject needs a separate study by itself.

Respiratory Movements of Glottis.—The primitive larynx is closed except when air is passing; the larynx in higher mammals is open except when food is passing. The movements in man at inspiration and expiration are due, in part, to this primitive mechanism, and also to the fact that the larynx is only a specialised part of the tracheo-bronchial tree, and that the whole of the latter dilates at inspiration to such in fresh air, and contracts at expiration to expel used-up air. Furthermore, the amount of dead spare air is considerably diminished by these movements. Contraction and dilatation of the trachea are much greater in some fast-running animals than in slower man, and the amount of muscle tissue is proportionally increased.

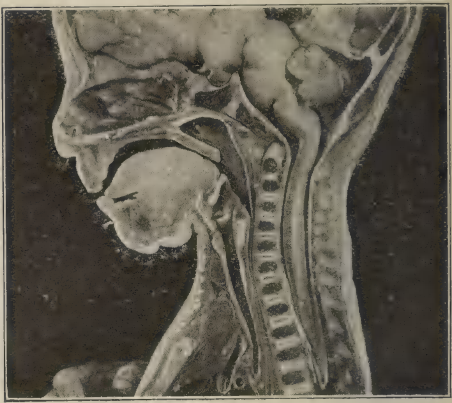
EFFECTS ON CIRCULATION.

Sir Arthur Keith has brought to my notice, and impressed on me the importance of, the influence of movements at the glottis on circulation in the lungs; I have also derived much information on this subject from Prof. J. S. McDowall. The glottis in man is usually not quite fully dilated during inspiration, and because of this, and also owing to the narrowness of the aperture, slight obstruction is given to the inrushing air. Intra-thoracic pressure must therefore be less than atmospheric pressure for a short interval; blood is drawn into the right auricle because of the diminished pressure on the pericardium, and the right ventricle obtains a larger supply. At the same time the lowered intra-alveolar air pressure causes the pulmonary capillaries to dilate, so that a more free and more rapid circulation of blood passes through them to the left side of the heart; the left ventricle pumps out more blood, and the aortic pressure rises. During expiration the slight obstruction offered by the narrow and partly closed glottis produces a considerably raised intra-thoracic pressure, so that the pulmonary capillaries are compressed and the pulmonary circulation is retarded; consequently the aortic blood pressure falls. There is, however, a certain amount of compensation, because of the fact that some blood is squeezed out of the lungs into the left side of the heart.

FIG. IV.



Head of a seventh month fœtus in median sagittal section. (From a photograph by Henry George.)

To help in maintaining an efficient pulmonary circulation, the movements of the glottis vary in accordance with the needs of the individual, and increase on exertion. The mechanism is not present in Fish, Amphibians, and some Reptiles, but is one found only in animals whose breathing depends in part on suction—that is to say, it is only present in those animals which suck air into the lungs by the movements of the ribs and diaphragm. In the lower Reptiles air is pumped into the lungs by various mechanisms, and it is therefore impossible for a condition of negative intra-pulmonary pressure to occur; the conditions are the same as in a Mammal on which artificial respiration is carried out by a pump. In fast-running animals the design of the glottis is such as to offer as little resistance as possible to the passage of air; it is probable, however, that in them such respiratory glottic movements as occur play a part just as in the case of man.

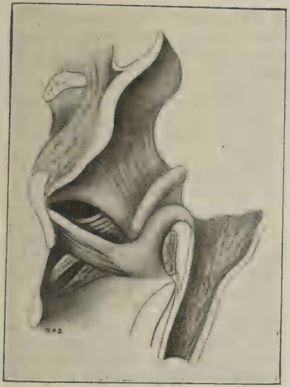
MODIFICATIONS FOR PURPOSES OF DEGLUTITION.

Protection of the Air Tract During Deglutition.—The pulmonary outgrowth springs from the middle line in the floor of the fore-gut, partly because that is a point of little resistance; the larynx has been shown to develop relations with the nose for various reasons, but it is to be emphasised that it is not guided in its earliest forms by considerations of future relation to the nasal tube. Air enters in very low types by the mouth, and as the path of evolution is traced up there is to be found in all cases a continuation of this close relation of air tract and food passage. When nasal respiration is firmly established there is still a necessity for crossing of the two streams; if the lung bud had grown out of the dorsal wall of the fore-gut, as it does in fact, in some fishes, the trachea and nose might well have been brought into such close relation that no larynx would have been needed. As Mr. Alex. R. Tweedie has pointed out to me, there would have been a corresponding loss in powers of phonation.

Deglutition in Reptiles.—There are various mechanisms for preventing the entrance of food and water into the air passages. In Reptiles this takes the form of simple apposition of arytenoids and thyro-arytenoid folds, by means of the sphincteric muscle; there is no epiglottis, and there is no process of mastication.

Use of Epiglottis.—In mammals with a simple larynx, such as Marsupials and the Cat tribe, closure is of much the same type, except that during the swallowing of liquids help may be derived from the epiglottis, which has been evolved primarily for other purposes. The epiglottic cartilage has attached to it lateral folds, and these, in conjunction with the posterior palatine folds, cause the production of a lateral food channel, along which liquids may pass, probably without complete closure of the glottis or movement of the epiglottis away from the nasopharynx. When a large bolus is swallowed, however, the epiglottis is drawn away from the raised soft palate up to the base of the tongue by means of the hyo-glosso-epiglottic muscle, and the glottis is closed by sphincteric muscular action.

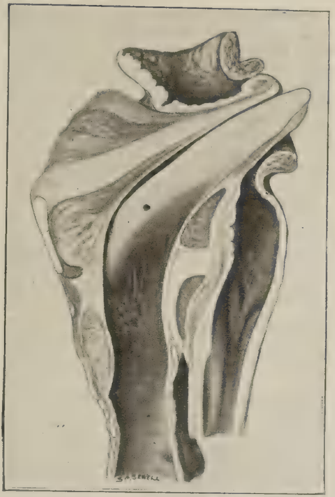
FIG. V.



Modification for purposes of deglutition. Median sagittal section of larynx of man of 50. (From a drawing by S. A. Sewell.)

Swallowing of Liquids in Man.—In chewing animals and in man the lateral food channel is made more efficient by means of aryteno-epiglottic folds, which protect the margins of the glottis from the entrance of food or water more efficiently than do lateral epiglottic folds. As the former take on this function, so the latter disappear, and in man they are absent. It is seen, then, that the epiglottis is called in to help during the swallowing of liquid: it is of little assistance when a solid bolus is passing (Fig. V.). When the ary-epiglottic folds are high and thin, as in man, there are developed in them supporting struts—namely, the cartilages of Wrisberg; their origin from the epiglottic cartilage has been dealt with fully by Göppert. They are almost always well developed in the human larynx, and by virtue of their presence the respiratory movements of the arytenoid cartilages are not interfered with; they reach their greatest development in whales and dolphins (Fig. VI.), if I am correct, and in conjunction with a complete arcus palato-pharyngeus enable simultaneous respiration and deglutition to occur. It is probable that they permit a similar action to take place in the human infant, and also in those with the power of pouring pints of beer down their throats while breathing.

FIG. VI.



Modification for purposes of deglutition. Median sagittal section of larynx of dolphin (*Delphinus delphis*). No. 1169E, Mus. Roy. Coll. Surg. (From a drawing by S. A. Sewell.)

Swallowing of Solids in Man.—When solid masses or large quantities of liquid are passing into the œsophagus, the whole larynx with the epiglottis is pulled up to the base of the tongue. The epiglottis is not sufficiently large, nor does its position call for the presence of a hyo-epiglottic muscle; the latter is represented by a rudimentary hyo-epiglottic ligament.

Closure of the laryngeal aperture is brought about by the action of the various divisions of the sphincteric muscle—namely, thyro-arytenoid, thyro-epiglottic, ary-epiglottic, and inter-arytenoid. The arytenoid cartilages are approximated to each other and drawn towards the cushion of the epiglottis, and the cartilages of Wrisberg are similarly dealt with by fibres of the external thyro-arytenoid. The aperture of the larynx thereby closes in a T-shaped manner; the action is facilitated by the power of rotation of the cricoid on the thyroid, an action not possible in low forms.

The inter-arytenoid muscle runs underneath the hook-like processes of Santorini and tilts them forward as it contracts in this action; to provide an articulation for this purpose there is present in the muscle of many bolting animals, but not in man, a cartilage, probably a relic of the procricoid.

Functions of Cartilages of Santorini.—To the tips of the cartilages of Santorini are attached many fibres of the œsophageal aponeurosis, the suspension of the œsophagus, in fact, not being limited to attachment to the cricoid plate. When the cartilages are tilted forwards, the œsophagus is thus caused to open in a funnel-shaped manner, and so there occurs a beautiful mechanism by means of which the larynx is closed and the œsophagus is opened.

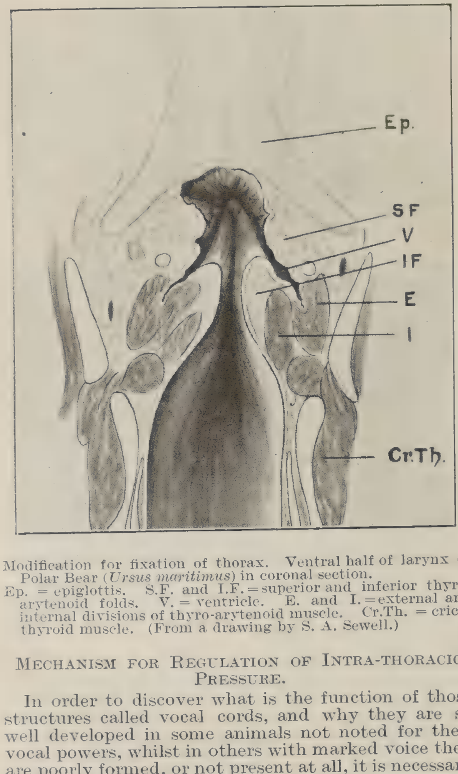
EXPULSION OF FOREIGN BODIES FROM AIR TRACT.

In coughing and sneezing a forced expiratory effort is made while the glottis is closed; when the air pressure has risen to a sufficient height the glottis opens, and the rush of air carries out mucus or other foreign bodies. In coughing the soft palate closes the naso-pharynx; in sneezing it leaves it partly open.

VOMITING AND AIR-SWALLOWING.

If an inspiratory effort be made with the vocal cords approximated to one another, and the crico-pharyngeal sphincter relaxed, air will enter the œsophagus; by closure of the crico-pharyngeus muscle and contraction of the œsophagus, the air can now be forced into the stomach. As a preliminary to vomiting, air-swallowing occurs; this is succeeded by violent emptying of the stomach. The glottis is closed and the thorax is compressed by muscular action until intra-thoracic pressure reaches a high level, when the laryngeal orifice suddenly blows open and allows an escaping blast of air to remove food débris from the upper air-passages.

FIG. VII.



Modification for fixation of thorax. Ventral half of larynx of Polar Bear (*Ursus maritimus*) in coronal section.

MECHANISM FOR REGULATION OF INTRA-THORACIC PRESSURE.

In order to discover what is the function of those structures called vocal cords, and why they are so well developed in some animals not noted for their vocal powers, whilst in others with marked voice they are poorly formed, or not present at all, it is necessary to examine all the habits of animals, and not merely the habit of phonation; it is possible by this means to discover whether there is any factor which has an influence on the valvular arrangements of the thyro-arytenoid folds.

Independent Use of Fore-limbs.—In man there is one habit in particular which has helped him to advance rapidly along the path of evolution and to excel other species, and that is the superior power he possesses of using his fore-limbs for actions independent of progression. Having graduated as an arboreal creature, he has learnt to hold on to the branches of trees, and later to weapons and implements; he has developed a prehensile thumb, and the power of holding small objects in a stationary position at arm's length. He can suspend the weight of his body from his arms, but with less ability than can most monkeys; he can also adduct his arms with considerable power. He has, in fact, a great advantage over those animals which use the fore-limb mainly as a pivot on which the weight of the trunk is poised, while the hind-limb pushes the body forward in progression.

When a man adducts his arms against pressure he stops breathing; this may be done either because it is impossible for him to go on breathing, or because he gains some mechanical advantage by the action; the latter is the correct explanation. It is desirable that the thorax should be brought to rest, so as to give a fixed point of origin to the various muscles arising from it, and especially to those which move the arm at the shoulder-joint, the pectoralis major in particular. As the pectoralis major contracts, two things may happen: either the ribs are elevated and inspiration aided, or else the arms are pulled inwards and downwards while the ribs remain stationary. To make certain that the latter action shall take place, the abdominal muscles contract and hold down the lower ribs, but it is highly probable that in most instances the action is assisted by the imprisonment of air in the thorax.

Negative Intra-thoracic Pressure.—As the ribs tend to rise, so the capacity of the thorax would be increased, and air would normally rush in to fill the enlarged space. But if a laryngoscopic examination be made of a man who is adducting his arms against pressure, it will be seen that the vocal cords close with a snap at the beginning of the action. As no air can enter the lungs to fill the enlarged space that would be created if the ribs were elevated—provided that the diaphragm be in partial contraction—it is obvious that the thoracic walls will tend to come to rest before the intra-thoracic air pressure has fallen to a low level. Owing to the potential or actual diminution in pressure within the chest, there is brought in a new factor to assist the muscles which fix the thorax, in the form of atmospheric pressure. The result is that the ribs attain a stationary position with less expenditure of energy than would be required if no vocal cords existed, and a fixed point of attachment to the muscles in question is provided for.

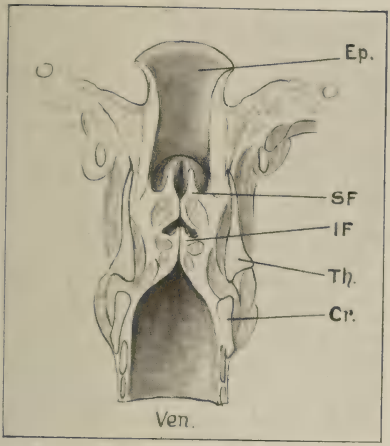
To control the changes of pressure produced it is certain that sphincteric action at the larynx is insufficient by itself, wherefore valvular action has to be brought into play, in the same manner as occurs in the heart, veins, ileo-cæcal valve, and other regions; the mechanism is, in fact, a favourite one in the body. It is found that almost all animals possessed of the power of independent use of the fore-limbs have also an inlet valve mechanism at the glottis, formed by what are usually called the vocal cords; animals that spring by means of the fore-limbs from a crouching attitude are similarly provided. Those animals without these habits have no valvular folds. Thus it is found that the Hare has no valves, but the Squirrel has; Sheep, Oxen, and Deer have none, but Bears, Lemurs, Monkeys, and Men have (Fig. VIII.). The Chimpanzee is of more arboreal habits than the Gorilla and has better valves; he has not better voice, however.

I have recently learnt from Prof. McDowall that temporarily diminished intrathoracic pressure does not necessarily cause stopping of the pulse, as Müller's experiment would lead us to believe; on the contrary, the aortic blood pressure is caused to rise, and the circulation is actually aided.

Positive Intrathoracic Pressure.—It is usually said that fixation of the thorax is attained by the taking of a deep inspiration and compression of the chest walls on this imprisoned air during closure of the glottis. Here, again, sphincteric action at the glottis is insufficient to withstand the high pressure produced, and valvular action again comes into play by means of the ventricular bands. The action certainly occurs in man at times, but I do not believe it is by any means the usual method during forearm efforts.

The ventricular bands are the free and undercut lower margins of the ary-epiglottic folds, and in a form capable of functioning as a valve they are almost entirely limited to the Gibbons, Chimpanzee, Orang, Gorilla, and Man. In practically all other animals the only valve available is one capable of preventing entrance of air into the lungs, and in consequence the mechanism of thoracic fixation by raised pressure would be one practically peculiar to the five species mentioned. (Fig. VII.) It is nevertheless true that many animals, apart from these five, can fix the thorax, and it is therefore to be supposed that they do so by the method of diminished pressure. It is necessary to discover what is the reason for the special mechanism found in the higher apes and man.

FIG. VIII.



Modification for fixation of thorax. Coronal section of larynx of Yellow-Fronted Lemur (*Lemur flavifrons*). Vocal cords and ventricular bands both capable of acting as inlet valves: there is no valvular arrangement for preventing exit of air.
Ep. = epiglottis. S.F. and I.F. = superior and inferior thyro-arytenoid folds. Th. = thyroid cartilage. Cr. = cricoid cartilage. Ven. = ventral half of larynx. (From a drawing by S. A. Sewell.)

Function of Ventricular Bands.—It is well known that in straining at stool the ventricular folds in man act as a valve, and that raised intrathoracic pressure is produced. It is possible that mobility of the upper ribs, present in Gibbons, the three other higher Apes, and man, gives a clue to the necessity for this special mechanism. Upper thoracic breathing has been described by Sir Arthur Keith as peculiar to the five species under discussion, and it is associated with mobility of the ribs. Contraction of the diaphragm in an effort to raise the intra-abdominal pressure tends to elevate the lower ribs. If the upper thorax is comparatively immobile, as it is in most animals, the lower ribs can be fixed and the diaphragm moves downwards and forwards as a piston; but if the upper thorax is freely mobile the ribs may move and the diaphragm remain stationary. Therefore, it seems probable that the ventricular bands are developed to act as a valve when it is desired to fill the thorax, and to retain the air under increased pressure. Thereby the ribs are spread, and the lower ribs are less likely to be elevated when the diaphragm contracts; consequently, the diaphragm has a more stationary attachment on which to exert its pull, and in its contraction will be able to raise intra-abdominal pressure with better results than would otherwise be obtained. Furthermore, when the thorax is full of air, its lower aperture has an increased diameter both transversely and antero-posteriorly, so that contraction of the diaphragm will take place at a mechanical advantage, and will cause a greater compression of the abdominal viscera if occurring while this position is maintained.

MODIFICATIONS FOR PHONATION.

I have attempted to explain that the larynx has taken up a certain position in order to subserve functions of olfaction and respiration, and that the peculiar situation it occupies in man can be understood if various structural characteristics of the human being are taken into account. I have endeavoured to show that the epiglottis was evolved for purposes of olfaction; the ary-epiglottic folds and cartilages of Wrisberg to provide a lateral food channel for the passage of liquids in animals which masticate their food; and the cartilage of Santorini as an important part of the mechanism by which the œsophagus is suspended and opened.

The arytenoid cartilages have been described as modified in length for respiratory reasons, and the muscles attached to them as concerned in the sphincteric closure of the larynx during deglutition, and in dilatation during respiration; the respiratory movements of the glottis were said to have a marked effect on the circulation of the blood. To those structures called vocal cords has been ascribed the function of preventing entry of air into the lungs for purposes of fixing the thorax, and the suggestion was made that valvular ventricular bands are concerned in the mechanism of raising intra-abdominal pressure in certain animals.

Because of these various observations, and because of a study of the vocal habits of animals in relation to the anatomical structure of the larynx in each species, the suggestion is reiterated that all mammals have an organ suitable for the production of sound, and that the extent of voice production depends in the main on the necessities and intelligence of the individual; some animals, however, and especially those of arboreal habits or arboreal ancestry, are better provided for than are others.

A discussion of the mechanism of phonation cannot be entered into here, but it will be sufficient to say that the evidence of comparative anatomy indicates, in my opinion, that variations in pitch of the voice are brought about by means of contraction and relaxation of the thyro-arytenoid muscles; and that raising of the pitch is due to increased contraction of these muscles, by virtue of which their elasticity is increased, while the rate at which they will recoil after being blown apart is accelerated.

This is a different view from that which ascribes to these muscles the function of relaxing the vocal cords, because in the former case the pitch would be raised by contraction of the muscles, while in the latter it would be lowered. I think that the attachment of the œsophagus to the cartilage of Santorini has an important function in the mechanism of phonation, but cannot elaborate the point in this paper; the evolution and mechanism of ary-vocalis muscle fibres must also be left out of account at present.

I would take this opportunity of recording my deep obligation for the privilege of permission to work in the laboratories of the Royal College of Surgeons of England, and also my sincere gratitude for the kindness extended to me by Sir Arthur Keith, who has given me invaluable advice and criticism in my work. I have also derived much information from Mr. Burne, and am very grateful to him. Acting on the advice of Sir StClair Thomson, Prof. Frazer, and Mr. T. B. Layton, I have attempted to learn something of the mechanism of the human larynx by the aid of comparative anatomy and physiology. In the study of the larynx of animals with this object, I am deeply indebted to Dr. C. F. Sonntag for placing at my disposal a wealth of material, and the use of the laboratories of the Zoological Society of London.

An Address
ON THE
FUNCTION OF HÆMOGLOBIN IN THE BODY.

Delivered at St. Mary's Hospital on May 8th in the course of lectures on Pathological Research in its Relation to Medicine.

BY A. V. HILL, F.R.S.,
PROFESSOR OF PHYSIOLOGY, UNIVERSITY COLLEGE, LONDON.

HÆMOGLOBIN has two main functions in the body—the carriage of oxygen and the carriage of acids, including CO_2; the modes of carriage are different, but equally important. That of oxygen has long been known, and its characteristics have been the subject of many investigations; that of acids and CO_2, though often discussed and doubted, at last seems certain beyond dispute. A possible third function of hæmoglobin has recently appeared from the work of Miss Robinson in Hopkins's laboratory at Cambridge. She found that hæmoglobin and its derivatives, methæmoglobin and hæmin, are able to accelerate very considerably the oxidation of unsaturated fatty acids—e.g., of linseed oil. Its non-iron containing derivative, hæmochromogen, produces, however, no such acceleration. The importance of this observation lies in the fact that a certain amount of hæmoglobin certainly lies inside the tissues themselves; it does not occur merely in the blood. Possibly its function in the tissues is that of an oxidative catalyst. This property of hæmoglobin appears not to be a consequence of its easily reversible combination with oxygen: it occurs equally in hæmin and methæmoglobin, or in hæmoglobin fully saturated with carbon monoxide. The fact that the katalytic action does not occur with hæmochromogen suggests that the accelerating power of hæmoglobin lies in its content of iron. Iron, as O. Warburg has found, is an important agent in katalysing many oxidations analogous to those occurring in the body. The action of hæmoglobin on the oxidation of unsaturated fats appears to be even more effective than that of an amount of inorganic iron equal to that contained in the hæmoglobin. It would seem possible that the faulty iron metabolism occurring in such conditions as anæmia may result in slow or defective oxidation in the tissues. This might be one cause of the dyspnœa associated with those conditions. I have discussed this possible function of hæmoglobin first since little is known about it, and we may now turn to the other functions which are better understood.

REASONS FOR EXISTENCE OF HÆMOGLOBIN INSIDE CORPUSCLES.

In nearly all animals hæmoglobin exists inside formed corpuscles in the circulating fluid; it does not usually occur simply dissolved in the plasma. There has been much speculation as to the cause, or function, of the packing away of the hæmoglobin into these formed elements. It may be partly due to the necessity of retaining the hæmoglobin molecule, which is comparatively small, inside the blood-vessels; were it not inside the corpuscle, it might diffuse freely from the plasma into the lymph and from the lymph into the tissues, and so its usual respiratory function would be wasted. It may be to save it from excretion by the kidneys, though, indeed, this end might have been achieved by making the kidneys impermeable to hæmoglobin, as they are in animals in which that substance is free in the plasma. The most important reason, however, is probably to enable this sensitive respiratory substance to be subjected to one set of conditions, while the plasma—and the tissues which it bathes—are subjected to another and more appropriate set. The physico-chemical conditions obtaining in the plasma may be appreciably, possibly widely, different from those inside the red corpuscle. By such means the body is provided, so to speak, with another degree of freedom. It may be able, as an adjustment or an acclimatisation, to change the conditions affecting the hæmoglobin without altering those obtaining in the plasma and in the lymph throughout the body.

THE COMBINATIONS OF HÆMOGLOBIN.

The hæmoglobin molecule contains an atom of iron. In its combination with oxygen the maximum amount of that gas with which it can combine is the chemical equivalent of the iron in the molecule. The ultimate unit of hæmoglobin appears to have a molecular weight of about 16,700; it is comparatively small therefore, the colloid molecule sharing many of the properties of crystalloids, being capable of crystallisation and obeying the laws of chemical mass action. It may combine also with carbon monoxide, a matter of great practical importance, since nearly all the deaths which occur in coal-mining are due to poisoning caused by the high affinity of CO for hæmoglobin. The CO-combination appears to be exactly of the same nature as that of oxygen. Hæmoglobin combines also with nitric oxide (NO), but that reaction has been little investigated owing to technical difficulties. The combinations of oxygen and carbon monoxide with hæmoglobin are reversible ones. At a low pressure only a small amount is taken up, at very low pressures practically none, at higher pressures, however, the hæmoglobin becomes fully saturated with the gas. If the pressure be reduced the gas originally combined will be again released. The important characteristics of these combinations can be shown in a curve which is known as the "dissociation curve." The degree of saturation of hæmoglobin is plotted vertically against the pressure of the gas horizontally (Fig. 1). The idea is simple but the technique difficult; it requires experience before accuracy can be attained. It is necessary first to expose the solution of hæmoglobin in a so-called "tonometer" or "saturator" to any required pressure of the gas, which must be analysed afterwards to ensure that it is finally of the expected composition. It must be revolved for some time under defined conditions of temperature in order to allow it fully to attain an equilibrium. The solution containing the gas in combination must then be removed and placed in a blood-gas apparatus of the type designed by Barcroft, Haldane, or Van Slyke. In this way the degree of saturation, or rather the degree of unsaturation, of hæmoglobin may be measured. Allowance must then be made for the gas dissolved in physical solution. So investigated, a dilute solution of hæmoglobin, or a strong solution very carefully dialysed to free it from salts, and adjusted to the right hydrogen-ion concentration, gives a dissociation curve which appears to be a rectangular hyperbola governed by a simple chemical equation. The presence, however, of salts in a strong solution, such as occurs inside the red blood corpuscle, was shown by Barcroft and his colleagues in a series of very fundamental observations some 15 years ago, very considerably to affect the shape of the curve, turning it from the simple hyperbolic type to one possessing an S-shape. It is a very fortunate thing for the body that the actual dissociation curve of blood is of the latter form and not of the former. Respiration would have been difficult had the blood possessed the properties of a dialysed solution of hæmoglobin. Owing to the S-shape, it is possible for the blood to take in its oxygen and to be fully saturated at not too great a pressure, and yet to give it off again at a pressure not so much less. The supply of oxygen to the tissues, from the blood in the capillaries, depends upon diffusion and requires, therefore, a comparatively large pressure—i.e., a concentration of the gas in order to drive it along. If the gas could be released from the hæmoglobin only at a very low pressure, as is the case with dialysed hæmoglobin, the removal by the tissues of a large fraction of the oxygen contained in the blood would be difficult or impossible. As it is, a high degree of utilisation of the oxygen contained in blood is rendered possible by the shape of the curve.

MOLECULAR CONSTITUTION OF HÆMOGLOBIN.

From the physico-chemical standpoint the change in shape produced in a strong solution by the presence of salts appears to be due to an aggregation, or a polymerisation of the hæmoglobin molecule, or to some other cause reducing what may be called its thermodynamic "activity." In a concentrated dialysed solution, or, as Hartridge and Roughton have recently shown, in a dilute solution undialysed, the reaction appears to follow the chemical equation,

$Hb + O_2 \rightleftarrows HbO_2$ (unaggregated molecules).

In concentrated solution, however, in the presence of salts, the molecules appear to be aggregated, and the chemical equation to be,

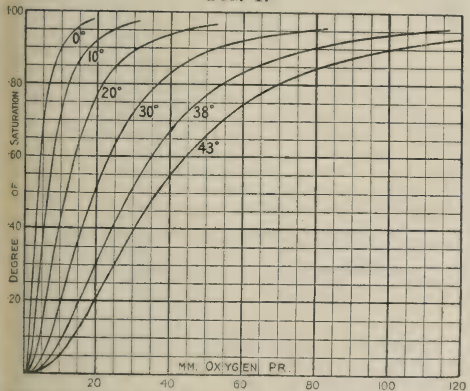
$Hb_n + nO_2 \rightleftarrows (HbO_2)_n$ (aggregated molecules).

The fundamental unit, therefore, of hæmoglobin, as it exists inside a red blood corpuscle, seems to be Hb_n containing n atoms of iron and combining with n molecules of oxygen. The quantity n seems to be an average number representing the average degree of aggregation of the molecule. Most of the molecules are present as Hb_2, a minority as Hb_3.

FACTORS AFFECTING DISSOCIATION CURVE.

The dissociation curve is affected by various factors. A rise of temperature, both in the case of dialysed hæmoglobin and in that of whole blood, produces a large fall in the affinity of the pigment for the gas. This is a thermodynamic consequence of the fact that hæmoglobin combines with oxygen with an evolution of heat. It is of importance in the body, since the highest temperature of the blood occurs in the most active tissues which need the oxygen most, and the high temperature helps to drive the oxygen out. The dissociation curve is affected also by a change in the hydrogen-ion concentration, whether produced by the presence of CO_2 or by the addition of acid—e.g., of lactic acid from the muscles—to the blood. The effect of CO_2 in diminishing the affinity of hæmoglobin is a large one and exactly similar to that produced by a rise of temperature: it is of importance both in the tissues and in the lungs, since the increased pressure of CO_2 in the capillaries of an active muscle helps to drive the oxygen out to the cells where it is wanted, whereas the diminished CO_2 in the lungs helps to allow oxygen to come in. The effect of fixed acid on the dissociation curve is important in connexion, both with asphyxia as was shown by Barcroft, and also with muscular exercise. The addition of 0·08 per cent. of lactic acid to blood, or even of 0·04 per cent., causes an extensive change in the form of the curve, a shift to the right (Fig. 1) similar to the shift produced by a rise of 5° C. Barcroft has shown that moderate exercise, such as walking up a mountain, may produce similar effects, which he attributed to the acid liberated by the muscles appearing in the blood. When it is remembered that severe muscular exercise may cause the appearance in the blood of as much as 170 mgm. of lactic acid in every 100 c.cm.—i.e., of 0·17 per cent.—it will be realised how extensive are the changes in the respiratory function of hæmoglobin which may be caused in this way. During severe muscular fatigue the blood, as a consequence of this effect of acid, may become more unsaturated as it passes through the capillaries, may have considerably more oxygen taken out of it at a given pressure than under normal circumstances—a fact for which the active muscles may well be grateful.

FIG. 1.



Dissociation curves of human blood, at different temperatures, and exposed to a CO_2 concentration which would have given a pressure of 40 mm. at 38° C. Calculated for $n = 2{\cdot}2$, $K_{38} = 0{\cdot}00060$, $q = 19000$ cals. (Plotted in terms of oxygen pressures at the actual temperatures involved, instead of in concentrations of oxygen.)

FIG. 2.

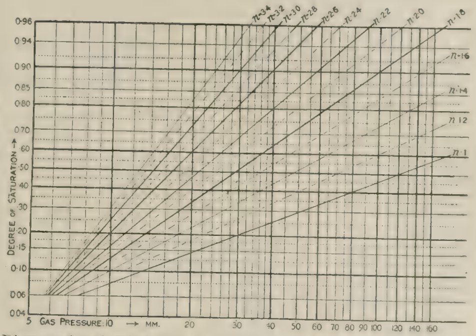


Diagram for plotting dissociation curves. Vertically log $y/(1-y)$ horizontally log x. If the observations obey the equation $y/(1-y) = Kx^n$, the points will lie on a straight line; the slope gives the value of n, which may be read directly on the diagram. A change in K only moves the line parallel to itself.

The equation of the dissociation curve, which may be deduced from the chemical formulæ given above, is $\frac{y}{1-y} = Kx^n$, with only two constants, K and n. Fortunately for the physico-chemical theory of the combination, the effect both of temperature and of a change in hydrogen-ion concentration appears to be directed at K only and not at n. K is largely diminished by a rise of temperature or of hydrogen-ion concentration, while n remains unaltered. This makes it possible to adopt a very simple form of dissociation curve, in which log $\frac{y}{1-y}$ is plotted vertically, and log x horizontally. The resulting dissociation curve thus becomes a straight line, which may be drawn with a ruler if two points upon it be known (Fig. 2); a change of temperature, or of hydrogen-ion concentration, merely moves this line backwards or forwards, parallel to itself, without changing its slope. This method of plotting dissociation curves, though it tells us nothing physically about the nature of the reactions, is a great help in the rapid drawing and interpolation of dissociation curves, and in demonstrating the effects of the two chief factors which change them. From the slope of the line the value of n may be read off.

This effect of acid on the dissociation curve is not confined to the case of oxygen. As Haldane and his colleagues have shown, CO_2 has an exactly similar effect upon the dissociation curves for carbon monoxide; on the distribution curves, however, of hæmoglobin between CO and O_2, acids and CO_2 have no effect. This may seem at first sight paradoxical, but when we remember that acid has the same effect on the CO dissociation curve as it has on the O_2 dissociation curve the result becomes obvious. There is no reason why it should work one way more than the other when both gases are present.

An explanation of why acid has this most important effect on the affinity of hæmoglobin for oxygen, or CO, has long been lacking. Recent work, however, has provided a tolerably certain one. Hæmoglobin, as it occurs in blood, is an electrolyte, a weak polyvalent acid. We may regard it therefore as dissociating according to the scheme:

$$H(Hb)_n \rightleftarrows H^{\cdot} + (Hb)'_n$$

in which the ion $(Hb)'_n$ has a very much greater affinity for the gas than has the molecule $H(Hb)_n$. Raising the hydrogen-ion concentration, therefore, tends, according to the laws of mass action, to depress the dissociation, to force the reaction to the left, to cause the formation of the undissociated molecule from the ions, and hence to produce a body having a smaller affinity for the gas. Raising the hydrogen-ion concentration, therefore, causes the hæmoglobin to give up its oxygen, raises the oxygen pressure. This process occurs in the capillaries; acid and CO_2 pass into the blood and help to drive the oxygen to the active cells which want it. Conversely, it is inevitable that raising the oxygen pressure should raise the hydrogen-ion concentration of blood. This effect has been shown directly by Parsons and more recently by Brown, indirectly—but equally certainly—by some observations of Haldane, of which I shall speak later.

METHOD OF CONVEYANCE OF ACID AND CO_2 BY BLOOD.

We will turn now to the question of how acid and CO_2 are carried by blood. It has long been disputed whether, on the one hand, CO_2 combines directly with hæmoglobin, either (1) as oxygen does, or (2) to form hæmoglobin carbonate or bicarbonate,

$$(1)\ Hb + CO_2 \rightleftarrows HbCO_2,\ \text{or}$$

$$(2)\ HbOH + H_2CO_3 \rightleftarrows HbHCO_3 + H_2O;$$

or whether, on the other hand, it is carried as bicarbonate by alkali released by the hæmoglobin or other weak acids in the blood,

$$NaHb + H_2CO_3 \longrightarrow NaHCO_3 + HHb.$$

It has been shown by Barcroft that the effect of CO_2 on the dissociation curve is precisely equal to that of the change in hydrogen-ion concentration which it produces. There is nothing left, therefore, for any specific effect: *CO_2 produces its change on the dissociation curve merely by its action as an acid* and in no other way. Conversely, therefore, hæmoglobin must deal with CO_2 as it would with an acid, not by any specific reaction such as that with oxygen and carbon monoxide. It is known, moreover, that in the ordinary range of CO_2 pressures there are no specific absorption bands corresponding to a direct compound of carbon dioxide and hæmoglobin. There would seem, therefore, to be only two possible ways in which the CO_2 could be dealt with: either the formation of sodium bicarbonate by means of sodium released by hæmoglobin, or the direct formation of hæmoglobin bicarbonate. The fact that CO_2 under all ordinary conditions is present simply as bicarbonate is shown, moreover, by the accuracy of the method of calculating the hydrogen-ion concentration by means of L. J. Henderson's equation,

$$cH = k.pCO_2/vCO_2.$$

If the term vCO_2 contained a large proportion present in some form other than bicarbonate, then the method would necessarily go astray; it is widely employed, however, and no serious discrepancies are found. Now an easy way of deciding whether the hæmoglobin combines with CO_2 directly, or liberates sodium to combine with it, is provided by the *determination of the sign of the electric charge on the hæmoglobin ion.* A recent, hitherto unpublished, research by H. Taylor has shown beyond question by electrometric methods that the hæmoglobin is there as an anion, carrying a total negative charge adequate to account for all the CO_2 which blood is capable of taking up. There is no doubt, therefore, that under ordinary circumstances hæmoglobin is present as the sodium or potassium salt of an acid —e.g., as Na_3Hb, an alkaline salt capable, like the salts of other weak acids, of acting as a "buffer," that is, of giving up its alkali to neutralise other and stronger acids. Such reactions as the following would occur:—

$$Na_3Hb + HX \longrightarrow Na_2HHb + NaX$$

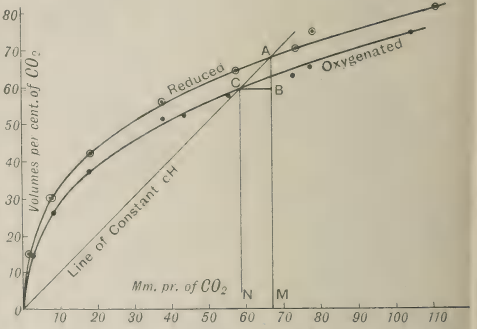
$$Na_2HHb + HX \longrightarrow NaH_2Hb + NaX.$$

Had there been hæmoglobin bicarbonate present, then the hæmoglobin would necessarily have had a *positive* electric charge; this is quite definitely not the case. As the CO_2 pressure is increased, the total charge on the hæmoglobin diminishes—as it should if the latter be present as an anion—and indeed by adding acid may be made to disappear altogether and become positive, though small, on the opposite side of the iso-electric point. This point, however, occurs well outside the range possessing any practical physiological significance. Such considerations show that CO_2 not only *may* be carried but *must* be carried in the manner indicated. One could wish that the certainty of these facts would induce people, who still hold the contrary view, to spend their time in the discussion of something more profitable.

IMPORTANCE OF CO_2 DISSOCIATION CURVE.

The CO_2 dissociation curve is of considerable importance (Fig. 3). It differs from the oxygen dissociation curve; it has no S-shape at the beginning; it does not approach a maximum, but continues to rise as the CO_2 pressure is increased. One of the most important—the most astonishing, the most intriguing—observations in connexion with the CO_2 dissociation curve was that made by Christiansen, Douglas, and Haldane on the effect of oxygen upon it. The combination of hæmoglobin with oxygen diminishes the amount of CO_2 with which the blood can combine! The explanation of this appears to be as follows. The hæmoglobin molecule is a very large one, with a number of groups on it capable of releasing a hydrogen ion and acting as an acid. At one particular group in the immediate neighbourhood of the iron atom very special conditions obtain, and when the iron combines with oxygen, as it probably does when that gas is taken up by hæmoglobin, the acid dissociation constant of the local hydrogen ion is very considerably increased. What was previously such a weak acid that it remained almost completely undissociated, has now become such a strong one that it becomes almost

FIG. 3.



CO_2 dissociation curves of oxygenated and reduced human blood (J. S. H.). Christiansen, Douglas, and Haldane, 1914.

completely dissociated and requires sodium to neutralise it. Consequently less sodium is available for the neutralisation of acids or CO_2, hence less CO_2 is capable of combining with the blood when oxygen has been taken up. This effect, which Haldane and his colleagues observed in 1914, is, as a matter of fact, a necessary consequence, from the physical standpoint, of the converse effect of CO_2 on the dissociation curves of blood. It is amusing to reflect that a phenomenon which could have been predicted from other well-known experimental facts had to wait for its discovery by actual experiment; it is strange how often one begins to predict only after the event! This effect of oxygen in changing the affinity of blood for CO_2 is of importance in the capillaries and lungs, in both of which it aids the transport of CO_2. It can scarcely be called an adaptation, for it deals with a definite inadaptable chemical property; it is a striking example, however, of the way in which the body is apt to find and utilise chemical reactions which seem so admirably to suit its purposes.

METHOD OF RETENTION OF HÆMOGLOBIN IN RED CELLS.

Hæmoglobin is retained inside the walls of the corpuscle by the presence of an impermeable membrane; so also are $Na^{\bullet}$, $K^{\bullet}$, and phosphate ions, but not $H^{\bullet}$ or Cl'. The wall of the corpuscle is very thin and elastic. Probably the total osmotic pressure inside it is equal to that outside. When the plasma has water or any chemical body added to it, the corpuscle swells or shrinks, so as to maintain an equality of osmotic pressure. The osmotic pressure of hæmoglobin is not inconsiderable and is probably balanced by the difference in the pressures of other indiffusible bodies, such as $Na^{\bullet}$, $K^{\bullet}$, and PO_4. By special methods it is possible to destroy the impermeability to $Na^{\bullet}$ and $K^{\bullet}$ while leaving that to Hb. If the boundary of the corpuscle be permeable to all salts, but not to hæmoglobin, the osmotic pressure of the latter necessarily causes the corpuscle to swell up. During the dialysis of blood corpuscles, without previous laking, this phenomenon was discovered by Barcroft, who found that the corpuscles swelled up into contact with one another, appearing to be a homogeneous solution, but becoming cloudy at once, as Brown showed later, by the addition of salts. The effect of adding salts is only temporary, and disappears as the salts distribute themselves evenly inside and outside the now permeable corpuscles; the latter then swell again under the osmotic pressure of the hæmoglobin inside. This experiment may be repeated again and again, the cloudiness appearing and then disappearing each time the salt is added. Another explanation of the phenomenon has been given by Brinkman, an explanation, however, requiring some credulity. It is supposed that the hæmoglobin in such cases is really outside in the solution, but that on the addition of salts it returns, by some process of adsorption or otherwise, to the inside of the corpuscle. A rough calculation, however, shows that if the hæmoglobin were distributed only on the surface of the corpuscle, it would form, not a monomolecular layer, but one about 100 molecules thick. It is difficult to see how it could hold on! Other explanations of the phenomenon than that advanced by Brinkman would seem more plausible.

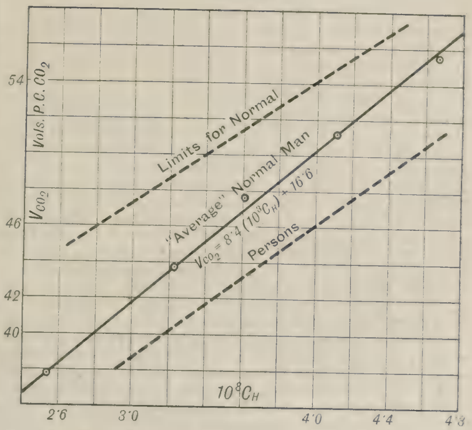
Bürker has described an interesting relation between the linear dimensions of a blood corpuscle and the amount of hæmoglobin which it contains. Over a wide range of animals the amount of hæmoglobin per corpuscle is apparently proportional to the surface of the latter. This also suggests, at first, that the hæmoglobin is connected with, or carried by, the surface of the cell. The amount, however, of hæmoglobin would seem to prohibit this explanation, since it is difficult to conceive adsorption, or any other physical process, to go on through a layer 100 molecules deep. It is far more likely, as L. E. Bayliss has suggested, that Bürker's relation depends upon the fact that the thickness of all the corpuscles is about the same, in which case their content of hæmoglobin would naturally be proportional to their area.

At the surface of the corpuscle there exists what is known as a Donnan membrane equilibrium. The presence in the corpuscle of charged ions, incapable of passing through its walls, produces a difference of electrical potential across its surface and a difference of concentration on its two sides of ions otherwise able freely to diffuse. This is not the occasion to discuss this membrane equilibrium, but it would seem certain that the differences which are known to exist, and the transformations which are known to occur, between the inside and the outside of the blood corpuscle, are due largely to the existence of this Donnan equilibrium.

"BUFFER" PROPERTY OF HÆMOGLOBIN.

The property possessed by hæmoglobin of acting as a weak acid which, in combination with alkali, is a very potent "buffer," explains the capacity of blood for holding—for neutralising—relatively large quantities of acid, without a serious rise of the hydrogen-ion concentration. Recent work by Barcroft and his colleagues has defined the relations which exist, in the blood of the average normal man, between the hydrogen-ion concentration and the CO_2 pressure on the one hand, and between the volume of CO_2 carried by the blood and the hydrogen-ion concentration on the other (Fig. 4). The steepness of the line, in the latter case, relating the volume of CO_2 carried in the blood to the hydrogen-ion concentration, is *a measure of the efficiency with which the blood is buffered;* the position of the line depends upon the amount of bicarbonate in the blood and may be altered by artificial means. Its slope, however, depends mainly upon the amount of hæmoglobin present in the blood; it will be less in the case of anæmic persons, more in that of persons acclimatised to high altitudes, with a high hæmoglobin content.

FIG. 4.



Normal human blood cH varied by varying CO_2 pressure. Relation between vCO_2 and cH. The heavy line, which is exactly straight, denotes the relation for the "average" normal man, the broken lines enclose the relations for eight normal persons. The steepness of the straight line is a measure of the efficiency of "buffering," and is determined mainly by the amount of hæmoglobin in the blood. Barcroft, Bock, &c., 1922.

TYPES OF HÆMOGLOBIN.

It has long been discussed whether all types of hæmoglobin are the same, or whether different animals each possess their own characteristic pigment. It was known, of course, that crystallographically the hæmoglobins of different animals were different: this, however, might be due merely to the specific globin portions of the molecules, and not be associated with any very striking physical or chemical differences. Recent work by Barcroft on the blood of a marine worm, *Arenicola*, has shown quite definitely that, both in its physical and its chemical properties, that animal, at any rate, possesses its own specific hæmoglobin. Barcroft's work was carried out with a wonderful little instrument, the Hartridge reversion spectroscope, which is becoming of more and more value in the study of the behaviour of hæmoglobin and blood. The principle of this instrument is not unlike that of the Barr and Stroud range-finder, in which two images are placed, one above the other, and a coincidence is obtained by the observer between corresponding lines or points. In the Hartridge instrument two spectra are placed, one above the other, one of them being reversed, and coincidence is obtained by placing two absorption bands in line. This method enables far greater accuracy to be attained than by the usual method, in the measurement of the wave-length of an absorption band, and has been adapted for determining the dissociation curves of dilute solutions of hæmoglobin, both with oxygen and CO. Employing Hartridge's instrument Barcroft found that the α-absorption-band of hæmoglobin from *Arenicola* is in quite a different place from that of human hæmoglobin, and—even more striking—that the distance between the CO α-band and the oxygen α-band is also very different. Correlated with these shifts in the α-band is a large change in affinity. The blood of *Arenicola* has an enormously greater affinity for oxygen, and a greater affinity for carbon monoxide, the latter, however, being increased nothing like so much as the former. Furthermore, Barcroft found that if we vary the animal, or the temperature, or the gas with which the hæmoglobin is combined, then under all conditions there is a linear relation between the affinity and the wave-length of the resulting α-band. Clearly there is something of a very fundamental physical character behind these observations. In any case, Barcroft has answered without question the long-debated problem of whether all types of hæmoglobin are the same, and has shown, moreover, the extraordinarily low pressures at which, in *Arenicola*, oxygen dissociation can take place. An animal which can utilise oxygen, which can reduce its hæmoglobin at these very low pressures, must have an amazingly effective oxidative mechanism.

Effect of CO on Capacity of Hæmoglobin for Oxygen.

There is one curious and paradoxical observation, which is the last that I will discuss. If blood be brought in contact with a mixture of CO and O_2, and the pressure of the CO be varied from a finite value towards zero, then the degree of saturation of the hæmoglobin with oxygen will change; it will rise at first as the CO pressure is diminished, and will fall again as the CO pressure becomes very low and ultimately vanishes. It would have seemed at first sight almost inevitable that, as the CO pressure fell, the amount of oxygen taken up would rise continuously; CO turns out O_2, its removal should allow more O_2 to combine. There is a physico-chemical explanation of why the apparently common-sense view is wrong. We might—after the event—have predicted that the oxygen concentration would fall again. Douglas, Haldane, and Haldane, in any case, established the experimental fact, which explains an earlier observation by Haldane and Lorrain Smith—viz., that the condition of mice exposed to a very low pressure of oxygen did not deteriorate, but actually improved, on the admission of a small amount of carbon monoxide into the chamber in which they were! It would seem possible—though perhaps unlikely—that the breathing of a small amount of carbon monoxide might be of assistance in this way in aiding mountain-climbers suffering from oxygen-want at extreme heights.

Directions of Future Research.

Hæmoglobin is one of the most interesting substances in the world. Many views are possible about it, and some of these views I have expressed here. Others you will find in books, particularly in Bayliss's "Principles of General Physiology." In 1919 Mr. Barcroft and I persuaded Sir William Bayliss to come to Cambridge to discuss with us, and with Dr. Hartridge, the problems of hæmoglobin. After our discussion I remember jestingly remarking that we ought to found a "Hæmoglobin Club"; Sir William Bayliss took the suggestion seriously, approached the Medical Research Council, and the "Hæmoglobin Committee" was formed. Much work has since been done; we have written, with great labour, and with many searchings of heart, a pamphlet on the reaction of the blood. Some of the most beautiful work of recent times, of a physico-chemical character, has been achieved by Hartridge and Roughton at Cambridge, on the chemical dynamics of hæmoglobin; my colleague Brown has established the validity of thermodynamic reasoning and chemical equations applied to the reactions of hæmoglobin. There is still, however, much to be done; one would like to know why the reaction between hæmoglobin, oxygen, and carbon monoxide is affected by light, the reason why the ion of hæmoglobin has so much greater an affinity for oxygen than has the molecule, the exact nature of the corpuscular envelope, and the origin of the equilibria which take place at its boundary. One would be glad to discover the chemical nature of hæmoglobin, and its manner of synthesis in the body. We know still very little, but we know enough to be quite sure that we are on the right lines in regarding the red blood corpuscle as a physico-chemical problem, and in investigating it by physico-chemical means.

THE POSOLOGY OF BEVERAGES

AS DETERMINED BY THE FRACTIONAL-DIURESIS TEST.

By Dr. P. L. VIOLLE,

CONSULTING PHYSICIAN AT VITTEL; DIRECTOR OF THE LABORATORY, INSTITUTE OF HYDROLOGY, PARIS.

In certain patients it is necessary to know what becomes of liquids ingested by them and traversing a more or less abnormal organism. It is important to learn how the water intake is absorbed, diffused throughout the tissues and body-fluids, and, finally, how it is eliminated by the kidneys. Such knowledge of the course of water within the organism, especially important in cardiac, renal, and cardiorenal cases, is indispensable in view of the following objects: (1) exact regulation of the quantity of beverages employed; (2) logical distribution of their intake throughout the 24 hours; (3) indication of the conditions under which the absorption, diffusion, and elimination of water may be most perfect.

The term "beverages" should include all liquids received by the organism. In considering the total water intake, the water present in various foods must be included, since it constitutes an important part of the daily ration of water supplied to the organism. For present purposes, however, the following discussion refers to the water present in beverages.

Huchard and Fiessinger long ago pointed out the necessity for restricting beverages in asystolic patients. Widal has insisted that physicians should continually interest themselves in the quantity of liquids to be prescribed in cases of nephritis and in the regulation of food and drink according to given indications and particular cases. No method for such regulation has been hitherto available. In a case of Bright's disease, the permeability of the kidney must be known not only for urea and chlorides, but also for water. Whoever undertakes the management of Bright's disease must be familiar with these three factors. In ascertaining the general renal permeability it is a mistake to depend upon any single method, such as the phenolsulphonephthalein test or the method of induced polyuria. The permeability for various substances must be determined, as Widal has clearly shown.

The fractional-diuresis test indicates the permeability for water. And, on account of the discrimination which it requires between renal and extra-renal factors, it supplies information concerning general disturbances in the water-content of the organism and permits recognition of causes and the regulation of beverages according to the pathogeny present. As with all tests based upon induced polyuria, the fractional-diuresis test includes a certain number of essentials. However, the latter have been reduced to the minimum compatible with the object in view. The test is essentially clinical and practical.

Description of Method.

The test must be made under four essential conditions: 1. With the stomach empty, because, after meals, the urinary elimination is normally retarded on account of portal hypertension accompanying digestion (this retardation constitutes true digestive opsiuria). 2. With the chlorides in equilibrium, since variations in the quantity of absorbed chlorides produce variations in the quantity of water eliminated. In practice, determination of chloride equilibrium is exceedingly simple, the only essential being to maintain a uniform chloride intake for at least two days (this necessity is simplified still further because cases dealt with are usually cardiac or renal, and ordinarily placed on a chloride-free regimen). 3. The test must be made twice, a one-day interval being preferably allowed. During the first test, the patient being erect, reclining during the second test. 4. The diurnal and nocturnal urine should be determined in certain cases, in which nycturia, continuing into the morning hours, may invalidate a test already begun, and the presence of nycturia is thus readily revealed.

Technique.

The bladder is first completely voided, the urine being rejected. With the patient erect or reclining, according to the order selected for the test, four portions of water, each of 200 g., are swallowed, at half-hour intervals. Following reception of the first portion, and until three half hours elapse after the last portion is swallowed, the patient urinates every half hour into a graduated receptacle, noting the quantity voided on each occasion. It is sometimes well to relieve the patient of responsibility by providing a series of six suitable graduates, into which the patient urinates successively, beginning at the left. The urinary elimination curve, showing the appearance, degree, retardation, and cessation of polyuria, may thus be noted at a glance. It is best always to note precisely the several quantities of urine collected.

Results Obtained.

Following the intake of 800 g. water, as described, induced polyuria normally occupies a period of six half hours. The first and sixth fractions of urine are about 35 c.cm. each, return to this quantity showing termination of the test. The normal sequence is shown as follows :—

Time (A.M.)	Grammes water taken.	Grammes urine collected.
7.0	200	—
7.30	200	35
8.0	200	60
8.30	200	180
9.0	—	300
9.30	—	220
10.0	—	35
	800	830

The quantity thus collected first should be about 35 or 45 c.cm. A larger quantity suggests nycturia, prolonged into the morning. If nycturia seem present the total 24-hour excretion should be collected in two periods on the following day. The diurnal urine is collected from 9 A.M. to 9 P.M., the patient remaining erect, either sitting or standing. The nocturnal urine is voided from 9 P.M. to 9 A.M., the patient reclining. Inversion of the normal quantity of urine voided diurnally and nocturnally shows the presence of nycturia. Normally, the diurnal urine constitutes about two-thirds the total 24-hour quantity.

The last quantity collected may be larger than the first. If it be about 60 to 70 c.cm. the test is incomplete and should be continued for another half hour. Such prolongation only shows still more clearly a delay in elimination already indicated by the quantities of urine previously collected. The clinostatic results should be compared with the orthostatic results, since such comparison permits diagnosis of atypical elimination and indicates the intake of liquid which may be desirable for each particular case, whose needs are shown by the test.

The test indicates three main groups of conditions, more or less closely approximated in various cases. The table indicates the three possibilities. It is well to emphasise again, at this point, the great importance of distinguishing nycturia and its effects on the test from induced polyuria of high degree. Error of this kind seriously affects the results.

Group.	Position.	Urine passed.	Interpretation.	
1	O C	Equal and normal.	No disturbance, renal or extra-renal.	
2	O C	Diminished Increased.	Cardio-vascular affections.	
3	O C	Equal and abnormal.	Disturbed water absorption	Stomach. Intestine. Liver.
			Disturbed water diffusion	Membrane permeability altered. Humoral disturbance, especially chloride-retention.
			Renal disturbance.	

O = orthostatic. C = clinostatic tests.
The term "equal" means approximately equal only.

In group 3 the test does not indicate the nature of the lesion producing defective elimination of water by the kidney, but shows that a lesion requiring diagnosis by the usual methods is present. Let us examine each of the three groups in detail.

Group 1.—Elimination is identical and normal, orthostatically or clinostatically. The absorption, diffusion, and elimination of water may therefore be considered unaffected, and renal and extra-renal conditions may be regarded as normal.

Group 2.—Clinostatic is better than orthostatic elimination. Cardiovascular disturbances, impeding the circulation of water within the organism, may be assumed to be present. Linossier and Lemoine have shown that orthostatic oliguria is caused by circulatory disturbances, the cardiovascular apparatus being defective while the secretory capacity of the kidney may be normal. Conditions in Group 2 must be closely scrutinised. If the orthostatic is less than the clinostatic elimination, the latter being normal, the cardiovascular affection present is of simple nature. For example, take the following elimination scheme :—

O	35	55	90	200	175	85
C	35	60	180	300	220	35

In this case estimation may be made by subtraction, the influence of cardiovascular factors in the urinary-water anomalies may be noted, functional cardiovascular disorder may be assumed, and cardiac insufficiency may be suggested, as Merklen has remarked.

If clinostatic elimination is abnormal, affections besides the cardiovascular disturbances exist. The combination is indicated as follows :—

O	35	55	90	200	175	85
C	35	55	120	230	180	70

Here the exact influence of the cardiovascular factors present cannot be determined by the scheme, because aggravating factors are superadded. We may now consider Group 3.

Group 3.—Orthostatic and clinostatic elimination are practically equal, and cardiovascular affections may be excluded. However, the elimination is abnormal in both positions. The abnormality may be due to failure of the water to reach the kidneys normally, or to defective renal secretion, renal impermeability to water permitting the latter to reach the kidneys normally without being fully eliminated.

These different factors may be duly distinguished by systematic clinical examination. It should first be determined whether water reaches the kidneys normally.

(*a*) Gastric evacuation may be delayed. Normally, 200 g. water, received by the empty stomach, remain there for five to six minutes. Longer delay is due to retarded evacuation, most commonly on account of gastric dilatation. Here water may remain in the stomach for five or six hours after ingestion, the fractional-diuresis test naturally showing considerable delay in diuresis. The kidneys behave as if no water had been swallowed. In certain cases, as shown by Surmont and Tiprez, the diuresis test may permit diagnosis of pyloric stenosis.

(*b*) Gastric evacuation being normal, intestinal absorption may be retarded. Intestinal absorption is especially governed by the portal tension. Increased portal tension delays absorption. Gilbert, Lereboullet, and Villaret have shown that hepatic affections rapidly produce portal hypertension through intrahepatic circulatory obstruction. Opsiuria occurring in such cases constitutes an early sign of hepatic alteration.

In intestinal affections, and especially diarrhœa, water is evacuated with the stools. In retarded elimination due to intestinal conditions, the kidneys are not affected. If anomalies in diuresis are not explained by supplementary renal examinations referring to albuminuria, azotemia, and the blood chlorides, clinical examination of the stomach, intestine, and liver is indicated.

(*c*) In the presence of a normal digestive tract, diffusion of water within the organism may be altered. After normal absorption by the digestive tract, water may not normally circulate within the organism if affected by the following factors: (1) alterations of the tissues rendering them more or less impermeable and resulting in obstruction, in various membranes, to the free passage of water; (2) humoral disturbances. The movements of water within the organism are determined by normal or pathological variations in humoral equilibrium. Working with Labbé, and basing our conclusions upon the numerous modern studies on colloids, lipoids, mineral substances, and hydrogen-ion concentration, we have believed it possible to indicate four equilibria of especial importance in the hydric exchanges. These four equilibria are osmotic, acido-basic, lipocytic, and mineral.

Retention or displacement of the circulating water may follow disturbance of one or more of these equilibric factors. Sodium chloride being the agent which practically predominates in hydric regulation, affections of the latter are reducible, in the last analysis, to retention of water produced through chlorides. Diuresis is therefore affected in such states. Altered diuresis, however, is not a guide to renal impermeability for water, which may be retained solely through the action of chlorides. Before œdema becomes apparent and clinically evident by pitting on pressure, as much as 5 to 6 litres of water may be retained within the tissues. If chloride retention of water be suspected, the serial test devised by Pasteur Vallery-Radot, and consisting in the ingestion of quantities of salt with successive weighing of the patient, should be utilised.

Functional Elasticity and Functional Capacity.

If complete clinical examination fully eliminates all but renal factors in the altered diuresis observed, the latter may be considered due to renal impermeability for water. In such cases, and from the viewpoint of aqueous diuresis, two conditions may be considered which I will term, respectively, functional elasticity and functional capacity of the kidney. Functional elasticity is the ability of the kidney to respond to the excretory requirements of the organism. Functional capacity corresponds to the maximal excretory ability of the kidney.

A normal kidney has great functional elasticity, responding readily to the excretory variations physiologically required of it. A diseased kidney, on the other hand, as Albarran has shown, tends to excrete a uniform quantity regardless of conditions present. The importance of knowing whether functional elasticity of the kidney really exists, and of exactly determining its degree and power of accommodation, may be readily understood. The fractional-diuresis test supplies information on this essential point, upon which depend the indications for restricting beverages in Bright's disease (without œdema).

In order to illuminate the discussion, we offer three analytical statements, obtained clinostatically, and showing retarded elimination assigned to the kidneys only, making the critical examination described above. The three outlines show progressively diminishing functional elasticity and eliminative retardation which is rendered still greater by diminution in functional capacity.

(*a*) C.cm. urine collected: 25, 30, 45, 120, 160, 70. The urine contains pus, blood, and traces of albumin. Blood pressure, systolic 17, diastolic 10.

(*b*) C.cm. urine: 15, 18, 65, 125, 80, 25. The urine contains a small quantity (0·16 g.) albumin. Blood-urea, 0·50. Blood pressure, systolic 22, diastolic 15.

(*c*) C.cm. urine: 40, 35, 35, 33, 35, 35. Albumin, 2 g. Blood-urea, 1·5 g. Blood pressure, systolic 28, diastolic 15.

In case (*a*), of 800 c.cm. water ingested, but 450 c.cm. are eliminated within the period fixed for the test. In (*b*) and (*c*) the respective elimination is of 325 and 213 c.cm. But much more important than the total elimination is the diminution in functional elasticity. In case (*a*) the kidneys give no material response before the fourth half hour. Then, under the first maximal influence following ingestion of the total of 800 c.cm. water, they excrete the maximal quantity permitted by their functional capacity, or 160 c.cm. only at the fifth half hour, the usual elimination being almost immediately resumed. The reduction in functional elasticity is clearly evident. The elasticity is not wholly abolished, however, and must be taken into account in arranging the water ration. The latter must not be so rigidly restricted for mere diminution, as it will be for entire loss, of the functional elasticity of the kidney. In case (*b*) the elasticity is still less, a feeble eliminative effort, which is immediately arrested, appearing not earlier than the fourth half hour. In case (*c*) functional elasticity is lost and the kidneys are absolutely incapable of reacting.

Tests should be repeated in order to show the state of the kidneys from time to time. Moreover, exact information as to the renal condition is obtainable only by repeating the tests. The importance of regulating the liquid intake is readily understood. For example, in case (*c*) but 213 of the 800 c.cm. water ingested are excreted in six half hours. The total blood mass is appreciably increased; the blood pressure, already high, is raised still further; headache, due both to urea retention and to high blood pressure, is aggravated, and vertigo occurs frequently. The test shows us that the patient, for the moment, is incapable of eliminating more than an average of 35 c.cm. urine per half hour. The liquid intake, including milk, must be rigidly limited to 35 c.cm. per half hour, whether referring to meals or to other periods, and must include water present in soups and, as far as estimation is possible, in all other foods as well. For a few foods the water content is as follows: Cereals and legumens 10 per cent. to 14 per cent., roots and tubers 75 per cent. to 90 per cent., fruits 85 per cent., bread 30 per cent to 40 per cent., meats 55 per cent. to 75 per cent., milk 75 per cent. to

90 per cent., cheese 35 per cent. to 45 per cent. In the case considered, the total 24-hour urinary elimination and the urinations are much diminished. With such diminution of functional capacity and elasticity urinary excretion cannot be increased, and the case is grave.

In some cases the functional capacity may be high enough to permit excretion of 55 to 80 c.cm. in the absence of functional elasticity. Under such conditions from 70 to 80 c.cm. liquid may be allowed per half hour, and the total 24-hour excretion of urine is readily rendered normal. In most cases functional elasticity exists in some degree, and the most favourable quantity of water allowed must be determined by varying the quantities used in the tests. The most favourable quantity permissible corresponds to the minimum which is followed by maximal elimination. In a word, the dosage of beverages for each particular case may be regulated by an exact knowledge of the factors affecting the elimination of water, and by evaluating the effects assignable to each factor.

Conclusions.

1. In cardiovascular affections beverages should be taken with the patient reclining, and preferably on awaking in the morning and on retiring for the night. As far as possible drinks should be taken in small quantities at a time and not during meals. In a general way beverages should be reduced in proportion to the degree of cardiac insufficiency present, or, in other words, in proportion to the difference between orthostatic and clinostatic elimination.

2. In delayed absorption from the digestive tract, (*a*) gastric dilatation may exist. In this case beverages should be taken only a long time after meals, and in small, divided doses, the patient lying recumbent. If (*b*) intestinal affections, such as profuse diarrhœa, be present, beverages need not be reduced, but should be so prescribed as to bring the total 24-hour quantity of urine as nearly normal as possible. If (*c*) pathological, and especially hepatic, portal hypertension exist, the quantity of liquids which produce most abundant elimination of urine should be determined by making a number of trials. Preferably beverages should not be taken with meals in order not to add physiological hypertension to the portal hypertension already present. Physiological opsiuria may thus be avoided.

3. In humoral disturbances, and especially in retention due to chlorides, the patient should not receive chlorides with the food, and the beverages should be nicely adjusted to the reduced but remarkably uniform elimination commonly present in cases of this kind, at least in fully developed dropsy accompanying nephritis.

4. In purely renal affections the suggestions already given should be followed, especially with reference to functional elasticity and capacity of the kidney.

5. In exceptional and atypical cases, which occur frequently, consideration of the many factors which may be present, with estimation of the importance of each one, should permit suitable regulation of the beverages to meet the needs of the case in hand.

Clinical and Laboratory Notes.

A CASE OF
CONGENITAL CARDIAC MALFORMATION WITH PULMONARY TUBERCULOSIS.

BY THOMPSON CAMPBELL, M.D. GLASG.,
MEDICAL SUPERINTENDENT, WEST RIDING COUNTY SANATORIUM, ILKLEY;

AND

HAROLD L. COULTHARD, M.D. GLASG., D.P.H. OXF.,
SENIOR ASSISTANT MEDICAL OFFICER TO THE SANATORIUM.

THE prolongation of life for 28 years in the case of a patient suffering from grave congenital cardiac defects and the terminal association of this condition with pulmonary tuberculosis would appear to be sufficiently rare to merit record. It is also remarkable that an individual with such cardiac conditions was able to attempt to work—first as a pit-pony lad and later to engage in light labour in a ganister work.

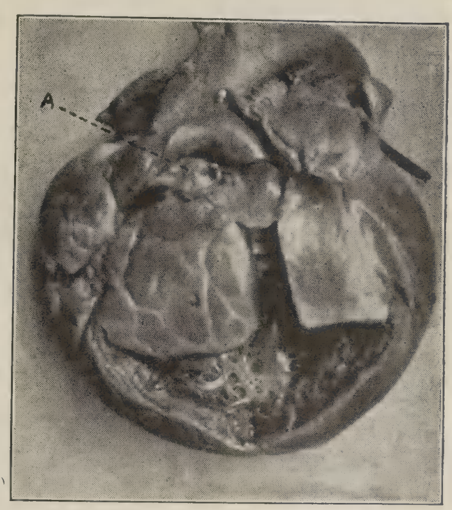
The patient, a male aged 28 years, was admitted to Middleton Sanatorium on Jan. 25th, 1923, on the recommendation of Dr. Samuel Bryson, district tuberculosis officer. The chief symptoms were cough, pain in the chest, dyspnœa, and cyanosis, the evidences of cardiac disease dating from birth and those of pulmonary tuberculosis from June, 1922. Slight hæmoptysis was reported six months before admission, and occasional recurrences. Clubbing of the fingers was present. The face, lips, ears, and fingers displayed the characteristic lividity. There was no marked dyspnœa at rest. On physical examination dullness was found over both lungs with feeble breath sounds and few râles; on each side of the sternum a bulging was evident between the levels of the third and sixth ribs. The area of præcordial dullness showed no extension to the left and there was no thrill. A prolonged blowing systolic murmur was audible, and the second pulmonic sound was noticeably weak. T.B. were present in the sputum, and an examination of the blood showed red cells to be 5,900,000 per c.mm. and white 6250 per c.mm.

Progress of Case.—The patient was confined to bed, and appeared to be fairly comfortable until 7 A.M. on Feb. 7th, when he was found in a state of grave syncope, having risen from bed in spite of prohibition to go to the lavatory, and five hours later a fatal result ensued.

Post-mortem examination revealed the following conditions.

Right lung: Apical adhesions. Marked venous congestion. Cavity of the size of a walnut filled with caseous debris at apex. Scattered tubercles throughout upper lobe and the upper third of lower lobe, the middle lobe being less affected.

FIG. 1.

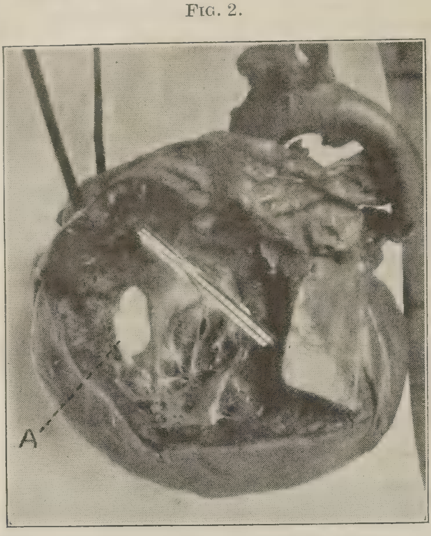


Showing pulmonary artery laid open, giving distal view of diaphragm formed by coalescence of semilunar valves (A), with small calibre opening.

Left lung: Apical adhesions. Marked venous congestion. Cavity at apex similar to that in right lung. Scattered tubercles throughout upper lobe and upper half of lower lobe. Base healthy.

Heart: Right auricle shows a wide patency of the foramen ovale, admitting the index finger with ease, also well-developed Eustachian valve, which is continuous with the valve of Thebesius. The opening of the tricuspid orifice is smaller than usual. Right ventricle shows considerable thickening of its right lateral and posterior wall, which is almost as thick as that of the left ventricle ; anteriorly the wall becomes very thin in the region of the conus arteriosus. The pulmonary valve presents adherent cusps with a central patency which admits only of the passage of a goose-quill, the surface being almost cartilaginous to the touch, and having an eroded appearance in the centre owing to the presence of hard vegetations. Similar calcareous excrescences are present on the ventricular surface of the cusps. The conus arteriosus shows a remarkable elongation and is dilated in the neighbourhood of the pulmonic cusps. The right papillary muscle is large, and projects chordæ tendineæ to the three cusps : the left papillary muscle is represented by a single chordæ tendinea. Posterior to the pedicle of the anterior papillary muscle is an oval opening through the fleshy inter-ventricular septum 3 cm. by 2 cm. in size, situated in its lower third. This channel between the ventricles is sacculated below by the interposition of a fine fibrous curtain coated with endothelium, which forms the lower border of the opening into the left ventricle and limits its extent. The mitral opening is larger than normal. There is a dilatation of the pulmonary artery distal to the adherent pulmonary valves. The ductus arteriosus is not persistent.

FIG. 2.



Showing aperture (A) in ventricular septum viewed through left ventricle.

The striking features of this case are : (1) The marked stenosis of the pulmonary artery through the close adhesion of the semilunar valves ; (2) the occurrence of the rarer warty form of endocarditis affecting the adherent pulmonic valves ; (3) the considerable size of the aperture in the inter-ventricular septum ; and (4) the marked patency of the foramen ovale.

The course of events in the early history of the organ would appear to have been as follows : The occurrence of endocarditis affecting valves of the pulmonary artery about the third or fourth month of fœtal life, when the ventricular septum was well developed but not closed, with consequent adhesion of the valves and obstruction to the blood flow. The over-charged right ventricle would then discharge part of its contents through the patent ventricular partition, and this considerable volume of blood would obviously prevent the normal closure of the septum. Similarly in the case of the inter-auricular septum, whereas at birth the augmented return flow of blood from the lungs normally tends to close the valve-like fold which forms during the fourth month of fœtal life,[1] this counter-pressure would be wanting owing to pulmonary artery obstruction, with the result that the foramen ovale would continue patent. This view is contrary to that expressed in the reference below,[2] but the fact that no developmental errors were found in other parts of the body in the present case lends support to the opinion that the original defect was due to endocarditis.

A CASE OF

STRANGULATION OF THE ILEUM BY AN INFLAMED APPENDIX.

BY IDA M. GUILLAUME, L.R.C.P. & S. EDIN.,
ANÆSTHETIST AND RESIDENT MEDICAL OFFICER, BARBADOS GENERAL HOSPITAL, WEST INDIES.

THIS case is recorded as an example of a rather unusual cause of strangulation of the bowel.

A negro, aged 15, was admitted to Barbados General Hospital under Dr. Gerald Manning on Feb. 21st, 1924, with a history of two days' abdominal pain, chiefly around the umbilicus, and no vomiting. In July, 1923, he had a somewhat similar attack overcome by high enemata, which had no effect this time.

Condition on Admission.—Temp. 98° F., pulse 40, later 60 ; abdominal facies, colicky attacks of pain referred to the umbilicus but no visible peristalsis, and an intensely tender painful tumour on right side, the largest part level with the umbilicus, and moderate abdominal distension. A high enema brought back a coloured result only, and the patient vomited bile four times.

Immediate operation showed that a large loop of greatly distended ileum, two feet long, was strangulated by the appendix looped around it in a tight ring, with the bulbous, swollen, and almost gangrenous tip adherent to its base at the cæcum and containing a fæcal concretion. The apex was freed, appendicectomy performed, the raw surface on the bowel sutured, and the whole returned to the abdomen. Wound healed by first intention.

Probably what occurred was that the long appendix kinked back on itself forming a loop ; the apex became blocked and finally inflamed and then adherent to the base in consequence ; a loop of ileum slipped through the ring so formed and became strangulated.

I am indebted to Dr. Gerald Manning for permission to publish this case.

CONGENITAL BONY OCCLUSION OF THE CHOANÆ.

BY ALBAN EVANS, M.R.C.S. ENG.,
SURGEON IN CHARGE EAR, NOSE AND THROAT DEPARTMENT, SWANSEA GENERAL HOSPITAL.

THE rarity of the condition should make the following case worthy of record.

D. W., male, aged 3 weeks, was brought to the out-patient department with a history of difficulty in breathing. Cyanosis and snuffling noticed soon after birth. Both sides of the nose were full of gelatinous mucus, and on probing a bony diaphragm was found completely blocking the choanæ.

The family history was interesting. Six years previously a baby had been born which survived 15 minutes. A year later came a second, which lived 24 hours. A third arrived the following year which lived for about 36 hours, and which had something wrong with the nose and throat. Two years later came a fourth baby which survived four and a half months, although blue all the time, which was attributed to heart disease.

The bony partition was thoroughly broken down. The baby had to be kept in hospital a month on account of digestive trouble, and when he left he appeared quite well.

LEWES VICTORIA HOSPITAL.—The accounts presented at the annual meeting of the governors of the hospital on May 6th showed a balance overdrawn on Dec. 31st of £169, as against £215 on Dec. 31st, 1922. The report stated that a new and up-to-date X ray apparatus had been installed at a cost of £399, and it was hoped the cost would be met without having to draw upon the invested funds. In 1914, when the system of private in-patients was started, the receipts were £61 ; in 1923 they totalled £275.

Medical Societies.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

A MEETING of this Society was held at Leeds on April 11th, Prof. E. O. CROFT being in the chair.

Blood Transfusion for Post-partum Hæmorrhage.

Dr. MCGREGOR YOUNG gave a report on blood transfusion for post-partum hæmorrhage at the Leeds Maternity Hospital, in cases where the patients presented all the signs and symptoms of impending death. Intravenous saline and gum solution had been tried without improvement or with relapse; four cases were placenta prævia, one accidental ante-partum, one hydatid mole, one abortion. All recovered; in three cases the improvement was immediate—in four cases after two hours. All were correctly grouped, except in one case on account of extreme urgency, but which did well. All the cases complained during transfusion of præcordial oppression and of fullness in head and neck. There was laboured breathing and cyanosis. On the other hand, no excruciating lumbar pains, no abnormal dropping of the pulse-rate, no high fever, and no hæmaturia followed, these latter being the signs of agglutination and hæmolysis from incorrect grouping. The probability is that the rate of transfusion was too rapid for unfilled veins and the empty right side of the heart, although usually 25 minutes were taken to transfuse a pint. Citrate of soda was used, about 4 ounces of 2 per cent. solution to the pint. A much prompter resort to blood transfusion was advocated where a donor could be found. Most of the disasters were due to delay.

Malposition of the Uterus after Delivery.

Dr. YOUNG also gave a report on 1000 consecutive deliveries examined on the twelfth day after labour at the Leeds Maternity Hospital with a view to malposition of the uterus. Retroversion was found in 50 cases—that is, 5 per cent. No pessary was inserted, nothing was done, and the patients were discharged without remarks. Most of these attended at intervals later. At the end of six months these 50 cases were asked to attend, and 32 came for re-examination. Of these 32 retroversions 30 were found normal and anteverted—that is, 93·7 per cent. —2 only remained retroverted, one from cause not apparent, the other from several fibroids in the posterior wall of the uterus. Cause for the puerperal retroversions was sought, but in 21 cases nothing apparent was found, the puerperium having been perfectly normal. In 6 cases there had been sapræmia of mild type, in 3 cases placenta prævia, and in 2 cases severe post-partum hæmorrhage. This report was thought to be of interest in view of (1) that it is a common routine to insert pessaries for puerperal retroversion in most maternity hospitals; (2) that it is the common teaching in most text-books that such treatment is the correct procedure.

Exhibition of Specimens: Chorion-Epithelioma of the Ovary.

Dr. D. DOUGAL (Manchester) showed a specimen of chorion-epithelioma of the ovary from a patient aged 29. Her first pregnancy terminated at seven months, two and a half years ago, the second at four months in March, 1922. Until Christmas, 1922, she menstruated every 5-6 weeks. A fall, with mild head injury, at Christmas was followed by vaginal bleeding which continued till September, 1923, when abdominal enlargement was first noticed. Amenorrhœa from September, 1923, till her admission to hospital five and a half months later. Pain in the left lower abdomen for several years, became worse with the onset of bleeding. During the present year there had been intermittent vomiting and the abdominal pain had increased in severity, being particularly acute on Feb. 6th and 13th. On admission she was thin and emaciated, her skin had a yellowish tinge; temperature normal; pulse 100; soreness in left lower abdomen. There was a tense, very tender tumour between the pubes and the umbilicus with its centre to the left of the middle line, suggesting a pregnant uterus with concealed hæmorrhage; the cervix was drawn up and pushed forward by an elastic swelling filling the pelvis and continuous with the abdominal swelling; the uterus appeared to be in front and to the right. Total hysterectomy with removal of both appendages was performed on March 1st, 1924. Straightforward convalescence and discharge from hospital four weeks later. The pelvis appeared to be quite clear. She reported at the out-patient department one week after discharge and a small swelling, the size of a tangerine, was felt high up on the left side close to the rectum. The specimen comprised (*a*) the uterus, soft and enlarged, endometrium 1 cm. thick, no visible growth in the uterus; histologically the endometrium had been transformed into decidua; (*b*) the right ovary, enlarged about four times, contained a number of small lutein cysts and some scattered lutein tissue; (*c*) on the left, the tumour, 6 × 5½ × 4 in., bright red in colour, surface nodular, partly covered above and in front by the broad ligament; the Fallopian tube ran around the upper anterior portion of the mass, the left ovary was merged in the tumour. Histological examination showed the tumour to be a chorion-epithelioma; posteriorly it is bounded by compressed layer of tunica albuginea with several follicular cysts; ovarian tissue is present in the centre of the mass, and in front is the remains of the broad ligament; the Fallopian tube can be traced from the uterine cornu to the outer pole of the tumour, and, although flattened by pressure, is normal throughout.

Dr. J. W. BURNS (Liverpool) showed an

Ectopic Gestation in a Tuberculous Fallopian Tube

from a patient aged 26. Four years ago she was confined to bed with reputed appendicitis. Menstruation, previously regular, ceased after June, 1923; three weeks' bleeding in September was followed by irregular hæmorrhages till operation for a tender, fixed right appendage swelling; the left appendage was also slightly enlarged and fixed. Both appendages were removed on Dec. 3rd, 1923. Both tubes showed tuberculous lesions and the right one contained blood-clot with degenerate villi.

Dr. FLETCHER SHAW (Manchester) reported a case of

Perineal Hæmatoma during Labour.

The patient was a primigravida, 39 years of age, and the hæmatoma was first noticed soon after labour commenced. It rapidly increased in size, and when he was called in to see her it had formed a large swelling all over the perineum, up both sides of the vulva, and into the recto-vaginal septum. It formed such a large tumour that he advised Cæsarean section. There was slight albuminuria present. The patient did quite well for two days after the operation, and then the intestines gradually became more and more paralysed and the patient died on the fifth day.

Messrs. W. Gough, M. H. Phillips, Leyland Robinson, and J. St. George Wilson showed specimens and cases, and Mr. Wilson and Dr. Dougal showed instruments.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held in the New Gallery, Edinburgh, on May 7th, Sir DAVID WALLACE, the President, being in the chair.

Dr. JAMES YOUNG read a communication on

Further Investigations into the Cause of Cancer.

After referring to the fact that many observers had isolated organisms from cancer tissue by incubation, Dr. Young went on to show how he had confirmed these findings and how his work would now seem to depend on the hypothesis that these organisms—yeasts, cocci, and bacilli—were different phases of the same parasite. This viewpoint was supported by extensive and rapidly growing evidence in recent literature. It had lately been shown possible to derive from cultures of the anthrax bacillus, yeasts, cocci, and branching filaments. In other words, these forms were to be regarded as merely phases in the life-history of the anthrax bacillus. Dr. Young suggested that as each phase could be rapidly stabilised and resist change, this had led to confusion in bacterial morphology. When a piece of cancer tissue was incubated in a test-tube the organism appeared in a variety of saprophytic forms derived from a phase so intimately locked up with the fresh tissue that it was ordinarily unrecognisable. Dr. Young demonstrated by means of micro-photographs what he believed to be the organism emerging from the cancer cell as plasm rods which went to form the inconspicuous and unstainable " plasm " or amorphous stage from which all the other organised types of the cancer organism were derived. He showed how the cocci, bacilli, or yeasts might develop from this plasm mass either directly or after passing through a second stage in which the " plasm " became encysted by a capsule rich in pigment. This he called the " sclerotical " stage. Hunter in 1892 showed that fungus elements were commonly found after incubating cancer tissue and a definite advance in the research had been accomplished by the discovery of this amorphous stage, which would seem to indicate that the parasite was definitely present in the cancer cell in this inconspicuous form, and, further, this form would appear to be toxi-potential. Dr. Young believed that the evidence he had brought forward supported the view that the cancer cell, like the tumour cell of plants, was a symbiotic compound of two living entities—the normal protoplasm and the parasitic plasm. In this connexion it was interesting to note that a plasm phase had recently been described in *Bacillus tumefaciens*, the causal organism of crown gall.

Discussion.

Prof. G. **LOVELL GULLAND** said that, as an old histologist, he doubted very much many of Dr. Young's conclusions for several reasons. It was well known that normal tissue when incubated often seemed to give rise to many strange forms of life—e.g., yeasts and cocci were commonly found—and he thought that, on further examination, many of the structures described by Dr. Young could be classified as products of degeneration. Cancer most commonly occurred on a free surface, and he suggested that, granted the presence of yeasts, as in cancer of the stomach, these might be of extrinsic origin. From the histological point of view he was always rather doubtful of unstainable material, and many, perhaps for this reason, were inclined to disregard it. Dr. Young, he thought, was inclined to place too much reliance on his " plasm " theory.

Sir **HAROLD STILES** described a visit to Irving Smith's laboratory where he had the opportunity of seeing for himself some of this worker's results with *Bacillus tumefaciens* in relation to crown gall. He had been much impressed, and though in the past he had spent time in endeavouring to disprove the organismal theory of cancer, he would now go so far as to say that he had quite an open mind on this subject.

Mr. **DOUGLAS GUTHRIE** read a paper, illustrated by lantern slides, on the

Styloid Process of the Temporal Bone: Its Variations and their Surgical Significance.

The two most frequent variations were abnormal length of the styloid process and the presence of a stylo-hyoid chain as in the lower animals. In the dog and horse the stylo-hyoid chain reached an advanced stage of development. In apes it was rudimentary, although the body of the hyoid bone was sometimes highly specialised so as to accommodate the laryngeal air sac. Man alone possessed a styloid process firmly ossified to the base of the skull. In the majority of instances those stylo-hyoid abnormalities were of purely anatomical interest, although occasionally cases occurred which gave rise to symptoms. A long incurved styloid process might project into the tonsillar region and thereby cause pain and difficulty of swallowing. After the operation of tonsillectomy, the tip of a long styloid might be found lying exposed in the tonsillar fossa. In the diagnosis the use of an X ray examination might prove helpful, and in regard to treatment the removal of the styloid was a fairly simple matter.

Mr. F. E. **JARDINE** then described a case where a medical man had mistaken this condition for a tonsillar calculus.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held on May 1st, Dr. G. M. **DUNCAN**, the President, being in the chair.

Dr. J. B. **DUGUID** read a paper on

Degenerative Conditions Found in the Aorta.

He stated that he had chosen the subject on account of the prevalent impression that atheroma was a condition found almost universally in the autopsies of those over 30 years of age. He had accordingly investigated the records of 100 consecutive post-mortem examinations, and noted the changes found in the aorta under the three headings of (*a*) atheroma, (*b*) syphilitic aortitis, and (*c*) superficial fatty change. Examinations in 48 cases showed no evidence of aortic degeneration, 27 showed definite nodular atheroma in varying degrees of severity, 11 showed definite syphilitic aortitis, 4 showed a state difficult to classify with certainty but suggestive of syphilitic disease, and 10 showed superficial fatty change. Of the total, 7 showed multiple changes. Dr. Duguid pointed out that the first group was not a collection of unusually young subjects, only 25 being under 40 years, and it was surprising to find so high a percentage of healthy aortas. In the 27 cases of definite atheroma the ages were between 55 and 74, and only one case of over 60 years showed no atheroma, from which one might conclude that atheroma was the disease of old age occurring in the aorta. After briefly describing the changes found in atheroma, the speaker indicated that it was a disease mostly affecting the descending aorta. Syphilitic aortitis was then described, and emphasis laid on the constancy with which it attacked the first part of the aorta with a more diffuse and more irregular destruction; and on the age-incidence, which was much lower than that of atheroma. From this, Dr. Duguid deduced that the lesion giving the so-called " murmur of old age " was unlikely to be a lesion of the first part of the aorta, as had been suggested, because the first part of the aorta was not the part commonly affected in the " disease of old age." In this deduction the state of the aortic valves was not considered, as the aortic orifice was regarded as a structure in the composition of the heart itself. The ten cases of superficial fatty change occurred in bodies of ages from 38 to 73, but this was not of importance, as the condition was found even in infants, especially in cases of death from burning. All but two of the cases observed had died from acute suppurative conditions, and the condition of the aorta could be regarded as an acute toxic state. The histology of the condition was described, and Dr. Duguid pointed out that, like the other definitely toxic condition, syphilis, it attacked often the first part of the aorta. From the infrequency of the incidence in the post-mortem room, he believed that this was a condition not specially related to atheroma or to syphilitic aortitis, and, further, that it was a disease capable of completely clearing up.

Exhibition of Specimens.

A demonstration of pathological specimens was given, the following being the exhibitors: Prof. J. Marnoch, Prof. T. Shennan, Mr. Alexander Mitchell, Dr. R. Richards: Specimens of surgical pathology. Dr. John Cruickshank: Photographs and specimens illustrating tumours in fish. Dr. Duncan: A series of microscopic slides of pathological states of the appendix. Dr. H. Edgar Smith: Specimens of tumours of the eyeball. Dr. Alexander Low: A series of stereoscopic photographs of various developmental anomalies in man and lower animals. A discussion of the exhibits followed.

Reviews and Notices of Books.

A TEXT-BOOK OF OPERATIVE DENTISTRY.

Fourth Edition. Edited by C. N. JOHNSON, M.A., L.D.S., D.D.S., F.A.C.D., Professor of Operative Dentistry, Chicago College of Dental Surgery. London: Heinemann. 1923. Pp. 1136. 60*s.*

IT is an instructive comment on the development of dentistry that this book, which is devoted almost exclusively to operative details, should extend to over 1100 pages without exhausting the subject. Indeed, the reader may feel that some very important branches of operative dentistry receive insufficient consideration, while others, such as the construction of crowns and bridges, are not described at all.

The book commences with an excellent description of the macroscopic anatomy of the teeth, and since a sound knowledge of the anatomy of the teeth is essential to successful conservative dentistry, such a section is a welcome feature. The illustrations are unusually good and convey the chief details admirably. A short account of the points of surgical importance appended to the description of each tooth would have added to the value of this section. In the account of the pulp it is stated that it does not contain lymphatics, and the writer goes on to say that this is of pathological interest. Schweitzer has, however, demonstrated the presence of lymphatics in the pulp, and his work has been confirmed by Dewey and Noyes, two American workers. There is an excellent chapter on asepsis in the operating room by A. E. Webster, which, if it be somewhat of a counsel of perfection, is none the less a sound and shrewd contribution. In this respect there is much room for improvement in dentistry. Though the days of the consulting-room which resembled a drawing-room are steadily passing, yet it cannot be said that the equipment of the average dental surgery has any logical relationship to the surgical principles on which dentistry is based. The chapter on cavity preparation follows on the lines laid down by G. V. Black and is in every way sufficient. The various filling materials and the methods of using them are described not too fully, but on the whole adequately, though we think that the allowance of two pages to silicate fillings is hardly sufficient. We do not find any mention of the method of using amalgam introduced by Sir Harry Baldwin, in which the amalgam is packed into wet cement. In this country the merits of this method in securing additional retention are widely recognised. A very full account of the technique of removing impacted third molar teeth is contributed by C. E. Kells. We are glad to note that the writer deprecates the routine extraction of the second molar as a preliminary to removal of the third molar. There can be no doubt that in the majority of cases it is unnecessary and gives little help. The special operation devised by Kells and described in detail appears to us to be needlessly complex and requires an unnecessarily large armamentarium.

The chapter on the difficult question of the treatment of pyorrhœa is disappointing. The author advocates the use of retainers for teeth which are loose. We had thought that the point of view which attempted to save teeth at all costs, irrespective of the pathological consequences of keeping teeth hopelessly loose through disease, had been abandoned. It belongs to the period when dentistry was a form of tooth carpentry and took little heed of pathology. More than half the book is taken up with an account of radiology and orthodontics. In America the majority of dentists have an X ray plant installed. In this country it is still comparatively uncommon for dentists to take their own radiographs. Yet the number is increasing, and no doubt this section of the book will prove a welcome one. The section on orthodontics is excellently written and sufficiently up to date to include an account of the muscle-training exercises devised by A. P. Rogers of Boston.

The book may be commended as a sound guide to the operations of dentistry.

THE ELEMENTS OF VITAL STATISTICS.

New edition. By Sir ARTHUR NEWSHOLME, K.C.B. George Allen and Unwin, Ltd. 1923. Pp. 623. 24*s.*

THE subject of vital statistics is not everyone's taste. Most people are content to leave it severely to those who either possess the odd capacity for enjoying it, or by some malignancy of fate are compelled to study it. Nevertheless, its importance is great. Only by examining records can the health of the community be measured and the effect of modern methods of life ascertained. Medicine without statistics would lose its clearest modern claim to rank as a science. So long ago as 1889 Sir Arthur Newsholme placed us in debt by writing a book on the subject which, after passing through several editions, was revised in 1899. Now he has entirely rewritten it and has added so much new matter that the book is more than twice the size of the original. It has become more a volume for the specialist who desires to be brought up to date in recent studies, than for the student making his first acquaintance with the subject. The most distinctive new element in the book is its appeal to American as well as to British readers, as evidenced by the introduction of much material drawn from United States Public Health Reports and other sources, material which is inclined to be overlooked in this country, and is convenient to have thus presented in compact form.

Familiarity with the earlier editions raised hopes that the author, now matured in experience and knowledge, would reach the height, only attained by the expert, of being able to make his subject attractive and appear simple to the tyro. New material and more trustworthy has appeared since 1899. The author has since then held high office in this country and has come into close touch with his American confrères. Nevertheless, the volume under review has in some respects not fulfilled our hopes. The student, attempting to grasp the geography of the forest of statistic fact, is likely to get more and more fogged by constant direction to seek elsewhere on page X or page Y in reports A to Z for further information; by doubts cast on the reliability of information when found; by difficulties presented to him in discovering by statistical method the meaning of national records. One chapter entitled Arithmetic of Elementary Statistics, but dealing with the modern methods, must be noticed unkindly. In the preface it is pointed out that the introduction of more elaborate methods has repelled many hygienists. There is little to wonder at in this, since the book before us is not the only one in which the subject is dealt with in a manner difficult to follow. Fundamental terms, such as "probable error," are not clearly defined. The "normal curve" is described as the form taken by the binomial $(p + q)^n$ when n is infinite. What inexperienced reader could follow this incomplete and not very accurate statement? On one page (p. 516), where an example is given of Poisson's formula, there are actually three arithmetical errors and then a comment is made that numbers must be large for the "formula to work," an expression quite inconsistent with the spirit of modern statistical methods, which is essentially logical. It is a pity this chapter falls so far short of excellence, for the subsequent criticism of the application of the methods shows common-sense and might, therefore, lead readers to think that the methods themselves were faulty.

The scope of the book is wide, dealing as it does with all fields of life from birth to death, and discussing population and death-rates, infant mortality, marriage and fertility, infectious and industrial diseases, life-tables, housing and poverty, as well as statistical method and the graphic presentation of statistics. Possibly a more rigorous selection of material would have made the book more readable, but with the wealth of the material at the disposal of the author the difficulty of deciding what to put in must have been great. Throughout the book runs the theme that health and social prosperity move *pari passu*, whether the general death-rate be considered or its component parts, contributed by tuberculosis, infant mortality, or zymotic diseases. Fertility is presented as an exception; it is lowest where the social standing is highest, and is in inverse relation to mental activity; it is highest in the lowest social grades, and is in direct relation to physical activity. It is well that these generalities should be brought out.

LOCAL ANÆSTHESIA.

Its Scientific Basis and Practical Use. By Prof. H. BRAUN. Translated and edited by MALCOLM L. HARRIS, M.D. London: Henry Kimpton. 1924. With 231 illustrations. Pp. 411. 25*s.*

IT is ten years since the appearance of the first translation in English of Braun's famous text-book. This was from the third German edition, and now that the German version is in its sixth revised edition Dr. Malcolm Harris has thought rightly that a new English edition is required. The book is not much more extensive than before, but though slightly smaller in size is more closely printed. The main features, of course, remain the same, but there is a good deal of new matter. This is particularly noticeable, perhaps, in those parts of the text dealing with poisonous effects of local anæsthetics, prolonged experience having brought to light dangers that were not previously anticipated. Sometimes, too, these have become evident through novel methods of introducing local anæsthetics—for example, in splanchnic and in sacral anæsthesia. Apothesine, which is unmentioned in the last English edition, receives a considerable paragraph to itself in this one. The editor has done his work well. The original text is closely adhered to throughout, and when original matter not in the text is introduced the fact is made plain. The present edition will, we have no doubt, increase the already high reputation of Braun's work.

L'HÉLIOTHÉRAPIE À L'ALTITUDE.

By Dr. GERMAIN MATHIEU. Paris: A. Maloine et fils. 1924. Pp. 325.

THE purpose of Dr. Mathieu's book is to convince the medical profession in France of the necessity of making use of the combined sun and altitude treatment, which Rollier has proved to be so efficacious in surgical tuberculosis. The author has had the advantage of a long stay at Leysin and has collected a large amount of information affecting various aspects of his subject. He gives an exhaustive statistical study of the results obtained in Rollier's clinic during the period 1913–1920. The plan of giving the proportion of patients cured during each half-year of treatment is a good one, as it affords an idea of the probable duration of treatment in each type of case. The functional condition of joint lesions after arrest of the disease is also dealt with and in most cases is surprisingly good. Some 20 pages are devoted to the subject of heliotherapy in pulmonary tuberculosis; in this chapter Dr. Mathieu reaches the conclusion that sun treatment, if properly carried out, is definitely beneficial and does not increase the risks of hæmorrhage and congestion. He attributes the disappointing results hitherto obtained chiefly to the spasmodic and pusillanimous way in which this treatment has been carried out, and to the lack of knowledge regarding the type of case in which it is indicated. No such brilliant results are likely to be obtained as in surgical cases, and the extra supervision necessary has made medical officers of sanatoriums unwilling to embark systematically on this form of treatment.

In subsequent chapters Dr. Mathieu deals with the technique of heliotherapy and gives a large number of meteorological data chiefly derived from Dorno; he finally enters into an interesting discussion concerning the mode of action of the sun-bath. Although this problem is at present incapable of solution, the facts of the case are presented in such a way as to provide plentiful stimulus to thought. The old view, that the curative action of sunlight was due mainly to the ultra-violet rays, lost ground when it was found that they were unable to penetrate more than 1/10 mm. of skin. Rollier's theory that cutaneous pigment might transform these rays into ones of longer wave-length has no foundation in experiment. On the other hand, the recent discovery that it is the ultra-violet rays that are most effective in the prevention of rickets, has again swayed opinion in the direction of the shorter wave-lengths.

The action of light in increasing the ease with which hæmoglobin parts with its oxygen, together with the high penetrating power of the visible rays (which are capable of raising the temperature of the subcutaneous tissues to 116° F.), is thought by Dr. Mathieu to account for the increase in metabolism and the marked muscular development so characteristic of the sun treatment. The fact that a high degree of immunity is developed in specific fevers accompanied by rashes suggests that the protective function of the skin may not be confined to preventing the germs of disease from entering the body, but may also be concerned with the production of antibodies as a second line of defence. Rollier's observation that the pigmented skin was unaffected during an outbreak of chicken-pox, Leuba's failure to make vaccination "take" on pigmented skin, and the fact that tuberculous patients who pigment well tend to have a good prognosis are given in support of the theory that a healthy, pigmented skin raises the immunity of the body.

In attempting to assess the relative importance of the various factors concerned in the helio-alpine treatment, Dr. Mathieu broaches a very difficult subject. His conclusion, "on clinical grounds," that sunlight is by far the most important factor is not supported by sufficient evidence to make it at all convincing; especially as no mention is made of the increase in metabolism caused by exposure of the surface of the body to cold air.

MEDICAL HISTORY.

Magistri Salernitani Nondum Cogniti. A Contribution to the History of the Medical School of Salerno. By Dr. PIETRO CAPPARONI. With a Foreword by Sir D'ARCY POWER, K.B.E., F.R.C.S. Eng., &c. London: John Bale, Sons and Danielsson, Ltd. 1923. Pp. 65. 15*s.*

THIS volume forms No. 2 of the Wellcome Research Studies in Medical History. Everything connected with Salerno is of interest to the medical profession, and we congratulate Dr. Capparoni on having made such notable additions to the already published and valuable researches of De Renzi and Piero Giacosa. Dr. Capparoni tells us that while on military duty at Salerno in 1916 he had the opportunity of studying an MS. belonging to the library of the Cathedral of Salerno. It contained the Liber Confratrum and an obituary of the Confraternity of the Cruciati which was founded during the Middle Ages in the chapel of St. Michael in the cathedral. Part of the MS. goes back to the latter half of the eleventh century. A number of names are those of medical men, some again of them being those of Scotsmen and Englishmen, and it was this fact that led Dr. Capparoni to make a careful examination of the MS. From these documents and sundry others he was able to obtain the names of 31 medical men unknown to De Renzi and additional details about 36 masters already known to him. Before entering on a description of the MS. and his researches therein, Dr. Capparoni gives a most interesting historical review of Salerno and its medical school which probably began somewhere about the eleventh century, though there had been a hospital as early as the year 820. The largest hospital was that founded by Matthew of Aiello in 1183. The five periods into which the history of this great school was divided by the late Prof. Modestino del Gaizo are as follows: (1) The Monastic Hospital and perhaps scholastic period (before 1000); (2) Renaissance of Classical Medicine (between 1000 and 1150); (3) period of popular hygienic medicine (twelfth century); (4) period of creation of surgical schools (thirteenth century); (5) period of decadence (from fourteenth century to 1811). The dates of the various scripts in the MS. run from about 1073 to the sixteenth century.

Dr. Capparoni has conferred a real benefit upon all those interested in the history of medicine. He gives his readers a number of illustrations reproduced from photographs of various leaves of the MS. and of other documents in the Cathedral of St. Matthew. Transcriptions of portions of many of these are given in a documentary appendix, and the only fault which we can find with the book is that the transcriptions have not attached to them the number of the plate to which they refer; this makes it difficult for anyone not an expert in palæography to identify them. However, Plates 7, 8, 10, 22, 23, and 25 are fairly easy to identify, although the script, owing to necessary reduction, is very small. Among other illustrations are a view of Salerno as it is to-day and two of the pulpits in the cathedral, most beautiful structures in Cosmato work. The first illustration (p. 34) also shows a magnificent Paschal candlestick in the same work. Altogether, the book is a joy both to read and to look at.

CONSTRUCTIVE CONSCIOUS CONTROL OF THE INDIVIDUAL.

By F. MATTHIAS ALEXANDER. With an Introduction by Prof. JOHN DEWEY. London: Methuen and Co. 1924. Pp. 317. 10*s.* 6*d.*

Prof. Dewey in his introduction, whilst admitting that Mr. Alexander's principles and procedure are hard to understand and accept, still leaves us in danger of rejecting them for their incomprehensibility. Man, we are told, cannot meet the complexities of civilised life because of his lack of sensory appreciation of his own movements. This is to be remedied by unlearning his bad habits and paying attention to the "means whereby" rather than to the "end in view," and this process is constructive conscious control, to be achieved by a course of training and manipulation at the hands of a teacher. It is not easy, by reading alone, to grasp how by this procedure what Prof. Dewey calls the greatest of all tasks can be executed—the task of rescuing mankind from "all but a universal state of confusion, discontent, and strife." Mr. Alexander is possibly an intuitionalist who arrives at conclusions valid for himself and those to whom he conveys his enthusiasm, and the conclusions of such a one cannot always be set forth in a manner convincing to others.

JOURNALS.

QUARTERLY JOURNAL OF MEDICINE.—The April number contains the following articles: The Variations in Gastric Secretion of the Normal Individual, by James R. Bell and William MacAdam. Observations conducted by means of fractional gastric analysis, on 20 consecutive days, upon the same normal individual under similar conditions led to the conclusion that a single fractional test-meal may not afford a typical representation of the true state of gastric secretion.—Arterial Elasticity in Man, by J. Crighton Bramwell. Observations were made upon the arterial elasticity both in health and disease, and the effects of variation of this function upon the circulation as a whole. Diastolic blood pressure is an important factor in determining arterial elasticity, which rapidly diminishes as the diastolic pressure rises. In arterial disease the elasticity becomes impaired, and its characteristic relationship to the pressure is no longer present.—Studies in Calcium and Phosphorus Metabolism: Part III., The Absorption of Calcium and Phosphorus and their Fixation in the Skeleton, by S. V. Telfer. Osteoporosis and rickets-like changes in the bones of puppies resulted from a dietary deficient in calcium but containing an adequate supply of phosphorus. The addition of calcium lactate alone to such a diet was sufficient to cause a normal skeletal development. Various factors concerned in the normal absorption of calcium and of phosphorus are discussed, and the fixation of phosphorus in the bones was found to be dependent upon the retention of calcium.—Renal Glycosuria: A Clinical and Metabolic Study, by F. G. Finley and I. M. Rabinowitch. Six cases of renal glycosuria which were observed at the Montreal General Hospital are described. These formed 2 per cent. of a total of 275 consecutive cases referred to the metabolic clinic as diabetics. The article closes with some observations upon carbohydrate metabolism.—The Association of Blue Sclerotics with Brittle Bones and Progressive Deafness, by William Stobie. Fragility of bones occurring in association with a dark blue discoloration of the sclerotics was first recorded by Eddowes in 1880. The author gives details of cases since published, and proceeds to describe a family in certain members of which this peculiarity existed, together with otosclerosis. The anomalies are transmitted directly, occur in males and in females, and do not appear to shorten life. The deafness does not usually appear before the second or the third decade. The colour of the sclerotics is well shown in the plate.—The Inorganic Phosphorus Content of Cerebro-spinal Fluid, by Henry Cohen. The normal inorganic phosphorus content was found to be 1·25 to 2 mg. per 100 c.cm. A definite increase occurs in meningitis, but not in encephalitis lethargica. In chronic diseases of the nervous system the increase is very slight. The rise in the acute forms of meningitis is thought to be due to a greater permeability of the cells of the choroid plexus.—The Proteins of the Serum in Cancer, by E. L. Kennaway. Loeper described in 1920 an increase in the globulin in blood serum in cancer. This excess is believed to be derived from the tumour. The author has made observations on 104 cases, including carcinoma, non-cancerous conditions, and normal individuals. He finds that in some advanced cases of carcinoma there is an increase in the serum globulin greater than that found in other conditions. Equally advanced cases, however, may show no such change. No operable case was met with in which the amount of globulin was abnormal. The method does not therefore appear to be one of diagnostic value.—A Clinical Blood Coagulometer, by Owen S. Gibbs. The principle of the new type of blood coagulometer described consists "in forming a bead of blood on a thin wire, which on being tilted allows the bead to run up and down . . . , at the moment of coagulation the bead stops and adheres to the wire." Contact of the blood with the body tissues shortens the coagulation-time, but this is not so in hæmophilia. Addition of fresh tissue juice or serum from an animal to hæmophilic blood causes coagulation at practically normal rates. The apparatus is illustrated by means of a plate.

THE LATE DR. W. A. PINNIGER.—The death occurred very suddenly at Brighton, on May 2nd, of Walter Augustus Pinniger, M.R.C.S., L.R.C.P. Lond., who had been in practice in Brighton for over 30 years. He was actively associated with the Brighton, Hove, and Preston Provident Dispensary for many years, and had an extensive private practice. Aged 74, he had only recently gone into retirement. Following a service in St. Margaret's Church, where he had been a sidesman and a trustee, the remains were interred in the Brighton and Preston Cemetery.

Reports and Analytical Records.

ADALIN; BUTOLAN; OPTARSON; THEOCIN SODIUM ACETATE; LUMINAL.

(Bayer Products Limited, 1, Warple-way, Uxbridge-road, London, W. 3.)

Adalin (bromdiethylacetylcarbamide) is an almost tasteless and odourless sedative and hypnotic and is recommended for use in cases of neurasthenia and such nervous conditions as are found before minor operations. Its safety is suggested by the fact that while the normal dose as a sedative is one to two tablets of 5 gr. each three or four times daily, and as a hypnotic two or three tablets half an hour before bed-time, as much as 125 gr. have been taken in a single dose without any undesirable effect other than protracted sleep. As a rule, it is well borne by the gastro-intestinal tract, while it does not seem to depress the heart. The tablets can be taken in a little cold water when prescribed as a sedative, and with a hot drink, the nature of which is ordered by the physician, when prescribed as a hypnotic.

Butolan. This is a brand of carbamic acid ester of p-oxydiphenylmethane, and is used as a remedy for oxyuriasis. In its ordinary form it is a crystalline powder almost insoluble in cold water and is practically tasteless. No disturbance of the digestive tract has been noticed after its administration, and animal experiments have shown that the ingestion of huge doses produced no ill-results. The active principle of butolan kills the oxyuris within five minutes in a 1/4000 dilution. The preparation is sold in compressed tablets of 7½ gr. each (0·5 g.), and the adult treatment is one tablet taken three times a day for a week. The course should be followed by an aperient. The average dose for children is half a tablet and for infants a quarter of a tablet, but children of 10 years may take the adult dose. In obstinate cases two courses of treatment may be necessary, but the second should not commence till eight days after the end of the first course, leaving time for the eggs of the parasite to mature.

Optarson is an amino salt of heptin chlorarsenic acid, containing about 30 per cent. of arsenic, and strychnine, its use being indicated in nervous conditions, exhaustion, and in convalescence following infectious diseases. Its tonic action is not attended with any signs of local irritation and no unpleasant odour is imparted to the breath, while its efficacy is prompt and increases with the progressive action of the arsenic. The remedy is supplied in packages containing 12 ampoules of 1·2 c.cm. solution, and the general dose is 1 c.cm. every other day by hypodermic injection. In delicate persons the injection should be given only twice a week to commence with.

Theocin sodium acetate (soluble theocin) is a synthetic reproduction of an alkaloid occurring in minute quantities in tea-leaves and possessing marked diuretic properties. It is closely allied to theobromine, and has distinctly diuretic effects. The dose of theocin sodium acetate is 2½ to 5 gr. two or three times daily dissolved in water, but it can also be given intravenously or in suppositories. The drug is supplied in bottles of 1 oz. and ½ oz., and in tubes containing 20 1½ gr. tablets.

Phenylethylmalonylurea, having the descriptive name phenobarbital, and the registered name "Luminal," is a synthetic hypnotic and sedative which occurs as a white powder with a slightly bitter taste and is almost insoluble in water. The Bayer brand is supplied in powder in ½ oz. and 1 oz. cartons, in ¼ gr. tablets in bottles of 100, and in 1½ gr. tablets in bottles of 50, and also in tubes of various quantities and strengths. In the treatment of epilepsy luminal has established itself even more widely on the Continent and in America than in this country, but we may recall that not long ago in our columns[1] Dr. Gordon Holmes confirmed the benefits that can be obtained by its use, particularly in idiopathic major epilepsy. The drug is first-cousin to veronal, and, like all sedatives, will reduce the number of convulsions in epileptics if given in large enough doses. In fact the ideal drug being one with the maximum anticonvulsive and minimum sedative effects, luminal, of all preparations, comes nearest to what is required. The drug is contra-indicated where there is great debility, arterio-sclerosis, marked pulmonary or cardiac disease, and nephritis. Even small doses should be employed cautiously. In epilepsy, the dose for which varies according to severity and frequency of attacks, the drug may be taken, apparently, for an indefinite period, the average dose for an adult being 1½ gr. given at night and in the more severe types 3 gr. or more daily. For children the dose is proportionately smaller, as it is when employed as a sedative.

"TABLOID" NUCLEO-LECITHIN COMPOUND.

(Burroughs Wellcome and Co., Snow Hill Buildings, London, E.C. 1.)

This substance is an addition to the comprehensive series of compressed products issued by this firm. It is a compound, in which nuclein, lecithin, and the glycerophosphates of calcium and potassium are combined in the following proportions:—

Nuclein	gr. ¼
Lecithin	gr. ½
Potassium glycerophosphate	gr. 1
Calcium glycerophosphate	gr. 1

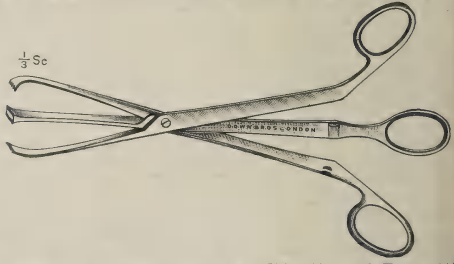
Nuclein has been claimed to possess a stimulating action in the formation of white blood corpuscles, thus raising the opsonic index and acting as a bactericide. The qualities and uses of lecithin are well known. The addition of the glycerophosphates of calcium and potassium is designed to exert a special selective action on the nervous system.

"Tabloid" Nucleo-Lecithin Compound is sugar-coated, so that the lecithin component is well disguised and at the same time protected from deterioration due to atmospheric action. The compound may be administered with any diet as a restorative, nutrient, and reconstituent in nervous and nutritional disorders. The drug is supplied in bottles of 25 and 100.

New Inventions.

A NEW THREE-BLADED PERITONEUM FORCEPS.

The instrument here illustrated will be found useful in grasping and bringing two raised peritoneal folds into position for suture, in an anastomosis, in sinking a bowel stump, or in invaginating a gastrostomy or cæcostomy tube. It is a modification of Pannett's three-bladed peritoneum forceps, the crushing blades of which are restricted in use to the parietal peritoneum. The multiple-toothed, non-crushing grip of Stiles's peritoneum forceps has been substituted for the crushing blade of Pannett's instrument.



Messrs. Down Bros., Ltd., St. Thomas's-street, London, S.E. 1, are the manufacturers.

Sheffield. Thos. B. Mouat, F.R.C.S. Eng.

THE LANCET.

LONDON: SATURDAY, MAY 17, 1924.

BIOCHEMISTRY.

CAMBRIDGE put on scarlet on Friday last to greet the Chancellor, to do honour to a great and well-loved teacher, and to open the new biochemical laboratories. Everyone will applaud the discretion of the trustees who have chosen the provision of an ample material field for the development of Prof. HOPKINS's activities as the best way of carrying out Sir WILLIAM DUNN's direction that his estate should be used "for the alleviation of human suffering." We are reminded of the simple motto which guides the benefactions of the Rockefeller Foundation—"the well-being of mankind throughout the world"—and it is a signal encouragement to the profession that the development of medicine along the broadest lines should be so generously recognised as one of the most hopeful roads towards human betterment.

No one need be very old to remember the time when biochemistry was not. Thirty years ago the English student of physiology was exhilarated by Dr. WOOLDRIDGE's translation of Bunge's Lectures which was published in 1890, and wondered at the erudition of Prof. HALLIBURTON's "Text-book of Chemical Physiology and Pathology" which appeared in the following year. There was a general feeling that those who sought to understand the working of the body ought to know its chemical composition as well as its minute anatomy, and courses of physiological study followed a rough grouping into experimental, chemical, and histological sections. Chemists as a whole were contemptuous of the messy slimes associated with life, though a change of heart was adumbrated by amiable disputes as to the relative merits of "chemical physiology" and "physiological chemistry." The mechanistic physiology of the nineteenth century was reaching its culmination, the impetus of DARWIN on biological studies was beginning to fade, and with the remarkable advances made by organic chemists in elucidating the chemical structure of some of the complex compounds associated with life a frame of mind arose which was convinced that the real key to the riddle of the difference between live and dead things lay in a knowledge of the chemistry of animate beings. The new impetus in inquiry was appropriately celebrated by a fresh word and "biochemistry" came into being, definitely perhaps in this country by the establishment of the *Biochemical Journal* by BENJAMIN MOORE and Mr. E. WHITLEY in 1906. And in these last 20 years it has been everywhere one of the most active and productive—quantitatively if not always qualitatively—of the departments of natural knowledge. The dream that it would quickly unlock the mystery of life has naturally not come true; it has perhaps not made any progress in that direction, it has sometimes even deflected the search into fruitless lines. Minute anatomists at one time felt sure that if only they could make the microscope magnify enough they would see life itself going on. But if biochemists and microscopists have both failed to realise their ideals, their energetic and enthusiastic pursuit of them has led to immense progress in method and knowledge.

The importance of biochemistry seems to lie in two directions. We still have the old distinction between "physiological chemists" and "chemical physiologists," between, for example, those who study the fate of β-phenyl-iso-butyric acid in the body in terms of its chemical constitution, and those who examine the influence of a cow's diet on the anti-rachitic value of its milk. But the enormous gain in the existence of a more or less independent discipline of biochemistry is that both groups of students now work in the same building, belong to the same society, and publish their results in the same journal. Biochemistry, in short, achieves what is so much needed in these times—a union and collaboration between two sections of scientific workers instead of a segregation and separation which has been the unfortunate result of the modern expansion and development. And it does this in the most effective way by its very nature, and without any of the useless scheming for coördination and integration of which so much is heard and so little seen. The chemist and biologist now lie down together; they desire knowledge and ensue it. And if physiological chemistry has not explained life it has made a surprising amount of progress in explaining the mechanisms of live animals and plants and how they work, partly along the lines of classical chemistry, more particularly in the field where the commingling of chemistry and physics shows again the fruitfulness of natural coöperation. That many harassed minds have found as much comfort in "colloids" as the old lady did in "Mesopotamia" does not detract from the really substantial progress in our understanding of how the body works which has been attained by knowing something of the properties of particles too big to be molecules, too small to be pieces of stuff. And in the same way the chemical physiologist has pushed forward with detailed explanations in almost every department of biology, and not least in the normal and abnormal human physiology which is the special concern of medicine. No further evidence is needed of the utility of the theory and practice of bio-chemistry in medicine than the change which has come over clinical laboratories in about the last 15 years. To the outfits for histology and bacteriology there is now everywhere added the armamentarium and the vocabulary of the chemist. The progress of bio-chemistry has been so ample and sound because it has begun and gone forward on a broad and generous basis, comparative as well as human, detached from, and yet intimately connected with, technology, furnishing food for the spirit as well as for the body. There is every prospect that in its new home at Cambridge it will continue its comprehensive career of catholic interests.

◆

THE USE OF THE GALL-BLADDER.

WHEN surgery becomes necessary in the treatment of gall-bladder disease the question more frequently than not arises as to the advisability of removal of the organ. Controversy on this subject has existed since the birth of gall-stone surgery, yet even now a completely satisfactory answer is not forthcoming. It is the old dilemma in which the surgeon is so often placed. He is called upon to take some active measure in the treatment of a disease which has already proved itself refractory to non-operative treatment; yet knowledge of the physiology, let alone the pathology, of the organ with which he has to deal is sadly wanting. Under these circumstances the evolution of the treatment of gall-bladder disease has been necessarily and commendably slow and cautious. Only now are such authorities as Sir Berkeley Moynihan and Mr. James Sherren, after observation extending over many years, able to recommend with confidence the excision of the gall-bladder in certain pathological conditions. The feasibility of this operation, on theoretical grounds, must obviously depend upon two considerations: whether the gall-bladder performs any important function in the physiological economy, and whether, should it be removed, its work can be vicariously performed by some other structure in the organism. The answer to the latter question has been given to this extent: many persons from whom the gall-bladder has been removed have lived long and apparently normal lives. They are free from the disturbances for which they sought aid, they have been restored to health. Progress, however, in the elucidation of the normal activities of the gall-bladder has been very slow. Only quite recently can it be said that any real knowledge has been gained. So resistant has this problem been to the attack of the investigator that many have held that the gall-bladder subserves no important function at all, that it is in fact an organ destined to disappear during the course of evolution, a structure which has outstayed its uses, assumed no new rôle, and has become rather a menace than a help to the organism.

The lecture[1] delivered before the American College of Physicians by Dr. J. E. Sweet, Professor of Surgical Research in the University of Pennsylvania, and now reprinted, forms an admirable example of the manner in which such problems should be attacked. He points out how important it is in a problem of this kind to approach it from every point of view. Its development, its structure, its comparative anatomy, the changes which take place when it is removed, all are capable of shedding light upon the physiological work of any organ. As to development, the gall-bladder is formed from the same group of ancestral cells which gives birth to such important structures as the stomach, duodenum, liver, and pancreas. From the way that it is disposed so that the fundus is lower than the apex, from the fact that the cystic duct is obstructed not only by being bent, but by the presence of mucosal valves, it is clearly seen that it is much easier for bile to enter its lumen than to escape. It does not look as though the contents were ever meant to emerge by way of the cystic duct. Nor have any experiments ever devised to demonstrate active expulsion by the contraction of its walls succeeded in doing so. The mural muscular tissue in microscopic section appears much more allied to the muscularis mucosæ than to the proper muscular coat of the intestinal wall. It is probably concerned with movements of the mucosa to facilitate absorption. The submucosa of the gall-bladder is unusually richly supplied with lymphatics, implying the possession of a strong absorptive function. This, indeed, the gall-bladder has been proved to exert by the experiments of Mann at the Mayo Clinic. Prof. Sweet calls attention to the little parietal sacculi seen in the extra- and intra-hepatic ducts described by Thiele, which Beale in 1889 regarded as supplementary gall-bladders. It is interesting to read that they are more numerous and bigger in those animals which do not possess a gall-bladder, as is also the fact that after cholecystectomy they increase in size and number. Prof. Sweet brings forward evidence to show that the gall-bladder is occupied with the metabolism of fats, so that one function at least seems definitely to have been assigned to the gall-bladder. It was always difficult to believe that an organ with such a very differentiated structure served only as a reservoir. The enigma of the gall-bladder, like other physiological problems, seems gradually to be yielding to well-planned experimental attack.

RESEARCH ON DISTEMPER.

The council appointed to administer the *Field* Distemper Fund, which has been instituted to further the investigation of this baffling disease in dogs, has recently issued a second report, which includes the recommendations of the Technical Scientific Committee presided over by Prof. C. J. Martin, F.R.S. The report sets out the encouraging financial support which has already been accorded to the scheme. It was estimated that £25,000 would be required in the first three years; about £9500 was received during the first year (1923), and future annual subscriptions to the amount of £3400 have been promised. The fund has therefore made a good start, but continued support will be needed if the investigation is to have a reasonable chance of success. After some delay, for which the council was not responsible, the specially isolated and equipped kennels and laboratories have been completed, and it is expected that the work in the isolation compound will begin forthwith. The first undertaking in this department concerns the breeding in isolation of healthy puppies for experiment.

The Medical Research Council is taking a large share in the investigation by allowing a part of its farm to be used for the premises designed for the research, and also by affording the veterinary experts the coöperation of the members of the scientific staff of the Hampstead Institute. This arrangement is a very suitable one, and will no doubt prove a fertile combination, since pathological problems in man and animals are largely identical. A number of human diseases are awaiting illumination derivable from animal experiment, but this help can only come indirectly, since the morbid states chiefly concerned are confined to man. The information which it is expected will accrue from the study of distemper, however, is expected to throw light on human disease, not only because distemper resembles in many ways influenza, measles, and such "zymotic" diseases, but because the basis of pathology as a whole will be widened. The experimental work of infection of animals with distemper has not yet begun, but preliminary work has already yielded interesting results, and the study of filter-passing viruses in general has been under survey, especially with a view to artificial culture. In spite of the fact that recent writers on distemper (Ferry, McGowan, Torrey, 1910–13) have pronounced after extensive investigations in favour of the *Bacillus bronchisepticus* as the cause of the disease, expert opinion has by no means entirely accepted this verdict, and an ultra-microscopic virus such as Carré believed that he had established has received wide support. The main reasons for this attitude of scepticism towards the bacillary hypothesis have been three: (1) the great difficulty which investigators have experienced in isolating experimental animals, so as to avoid unforeseen sources of infection which would render the results of inoculation open to question; (2) the somewhat indefinite characterisation of the bacillus in question, as distinct from other widespread strains or species—e.g., *B. fæcalis alkaligenes*; (3) the rather incomplete picture of the disease following the inoculation of cultures.

During the past few months 23 cases of typical canine distemper occurring in the London area have been examined post mortem by Mr. R. E. Glover, M.R.C.V.S., in the laboratories of the National Institute for Medical Research, and *B. bronchisepticus* has been sought in the various organs. It was only found in a small fraction of the cases; twice it was isolated from the tracheal mucous membrane of the 23 dogs examined, and three times from the bronchopneumonic lungs present in 17 of the animals. It cannot be said that this finding definitely negatives the bacterial theory of distemper, but a repetition of such a result on a larger scale might bring the matter much nearer settlement. The bacillus is easily cultivated, and consequently negative evidence as to its occurrence has a definite value. If the relation of *B. bronchisepticus* to distemper is not causal but only accidental or of the nature of a secondary infection, other localised epidemics unaccompanied by this bacillus are not unlikely to occur. The recent experience of Shoicho Kondo (1923) in Japan, however, again supports the claim of *B. bronchisepticus*. This worker was able to transmit the disease by inoculation of lung juice, but not when this had been filtered. From the affected lungs of 54 dogs suffering from distemper he isolated the bacillus 46 times, and believed that he gave the disease by injecting pure cultures. The same criticisms might be made of his work as of that of the writers quoted above, but since his paper is at present only available in abstract these would be premature. A world-wide association of *B. bronchisepticus* and distemper makes a strong suggestion of a causal relationship, but the history of an epidemic carefully investigated without the discovery of the bacillus would afford even more convincing evidence in the opposite sense. The great difficulties associated with the search for an ultra-microscopic virus are being seriously tackled at the laboratories of the National Institute for Medical Research with the very complete resources at the disposal of the scientific staff. An attempt is also being made to throw light on the epidemiology of distemper by the systematic collection of reports of outbreaks with a view to their statistical analysis.

Annotations.

"Ne quid nimis."

THE ORIGIN OF THE LARYNX.

THE larynx and the voice have been connected at least since the times of Aristotle and Hippocrates, and, in all probability, for centuries before their period. Galen described and named the laryngeal cartilages, gave an account of the muscles, and pointed to the glottic ligaments as the chief organ of the voice. We to-day are in the habit, in general, of talking of the larynx as the organ of the voice, and perhaps of implying indefinitely that the part came into being to serve the function of vocalisation. But teleological reasons for existence, although often and perforce admitted, cannot be estimated in terms of evolution, and it is well to be reminded that the larynx is not only the organ of voice, and to realise, from consideration of facts such as were brought forward in the Arris and Gale lecture by Mr. V. E. Negus (see p. 987) that it did not come into existence primarily as a sound-producer, nor was it evolved from its beginning in association with the growth of powers of vocalisation; it began life as a simple sphincteric valve at the entrance to the air-sacs or lungs, and it developed its other uses, by degrees, on top of its primary function. This way of looking at the larynx, of course, is not new, but Mr. Negus has brought forward some fresh matters which, as will be seen in his lecture, introduce new problems for consideration. The organ by means of which the voice is produced is undoubtedly the larynx, but many animals possess an instrument capable, to all appearances, of producing a range of tones like the human voice—yet they do not produce it. The difference between them and us lies, not in the instrument, but in the higher nervous connexions and the mentality, and the larynx is in reality but a structure which, owing to its convenient situation in the air-stream, has been utilised by the higher centres to serve this function in addition to its other and more primitive duties. It is interesting to note in this connexion that the human larynx is really a very simple structure. As in many other parts of the body, the brain has taken possession of a rather primitive instrument and has made it serve purposes which, without the guiding and governing brain, would call for much specialisation and intricacy of structure. Primitiveness and absence of specialisation are also of great value, almost of necessity, in the evolution of any organ up to the higher possibilities open to it. This primitive simplicity of the larynx, suggested at first by consideration of other types, becomes perhaps more apparent when we study its development. Mr. Negus has described the simple sphincter found in the primitive lung-fishes, and this simple sphincteric arrangement of developing muscle is found also in the young human embryo, surrounding the entrance to the air-way of the lungs. The sphincter is hardly disturbed by the formation of the cartilages; it is cut up into parts by their extension into it, but there is very little displacement of cells or fibres, and even in the adult larynx the sphincteric arrangement is still quite visible to those who look below the surface appearances of the muscles. The lower part of the larynx, the part below and including the glottis, is still primitively simple, and if its muscles do not act like a sphincter, it is only because the cartilages interfere mechanically with such an action. This is the part of the larynx more particularly concerned in voice production, the part which started its evolutionary career as a valve. The supra-glottic portion of the larynx is not derived from the walls of the air-tube, but is a modified part of the floor of the pharynx. Its development, away from the middle line, could have had nothing to do with the central and quite efficient valve, and its formation was a secondary and later one. Mr. Negus maintains that these pharyngeal structures were evolved in connexion with increasing efficiency in olfaction and deglutition after mastication. They are certainly of little direct value in phonation, although they may indirectly help in the performance of that function by relieving the region concerned of some of the burdens entailed by its more primitive duties. However this may be, it is of some interest to observe that the embryological and phylogenetic distinction between the lower and upper larynx has its reflection in the different lymphatic drainages of these two regions, as well as in other particulars. We cannot here follow Mr. Negus into many of the interesting possibilities which he has opened before us, but we may refer to one of these—the effect of the incomplete opening of the glottis in respiration on the intrathoracic pressure. The lessened intrathoracic pressure claimed as a result of this is no doubt an addition to that "negative pressure" which must exist normally in this region, as in the mediastinum, at all times. The naturally dilated condition of the thoracic œsophagus during life is an indication of this "negative" mediastinal pressure, and the alterations of pressure, described by Mr. Negus as producing certain effects on the pulmonary and aortic circulations, are perhaps to be regarded as curves of variation in the more constant and continuous effect which the mediastinal condition must produce on the venous inflow.

SODIUM SALICYLATE FOR ENCEPHALITIS LETHARGICA.

IN view of the prevalence of mild encephalitis at the present time, and the absence of any recognised successful form of treatment, the report of a case in a recent number of the *Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris* (April 10th, 1924) is of interest. A woman 21 years of age was admitted to hospital diagnosed as suffering from this disease, examination of the cerebro-spinal fluid revealing no abnormalities. An intravenous injection of 1 g. of sodium salicylate in a solution of 1 in 30 was given on the day of admission, and six days after the onset of the first symptom. Two days later the somnolence had disappeared and the headache, which had previously been very acute, was much less. The next day 2·65 g. were injected intravenously and salicylates were detected in the urine. The patient's condition remained satisfactory. Two days later, no further injection having been given, the somnolence had returned and was as marked as on admission, and the headache had reappeared. Myoclonic movements were beginning. Three grammes of sodium salicylate were thereupon injected intravenously, and within two hours the symptoms had disappeared. Attempts were made during the next few days to prevent the recurrence of symptoms by giving the drug by mouth, but without success, and recourse had to be made again to intravenous injections of 2·5 g. daily. After four more days all the symptoms had disappeared and they did not return after discontinuance of the drug.

THE MANCHESTER RADIUM INSTITUTE.

THE annual report of the work done at the Manchester and District Radium Institute during the last year has just reached us. The number of patients who presented themselves for treatment was slightly larger than in the previous year, being 829. Of these, 664 proved to be cases of malignant disease, while the remaining 165 suffered from various non-malignant diseases. During the same period a large number of radon plates and tubes were prepared by the physical staff attached to the Institute, and as some more radium has lately been purchased more emanation will be available for use next year. Dr. Arthur Burrows, radiologist to the Institute, states that 64 cases of malignant disease, exclusive of rodent ulcer, were rendered free from symptoms and signs of disease during the year. The result is satisfactory enough as far as it goes, but many of these cases can only have been treated within a few months of writing the report, and the question of permanent benefit must be judged after a longer interval of time. A laboratory for research has just been built and fitted up. This is a most important and necessary adjunct to any institute or hospital where the treatment of cancer is carried out with radium, and the two departments will be able to work in close conjunction.

Diathermy appears to give satisfactory results at Manchester, and is used in many cases of carcinoma, particularly in large fungating growths of the breast, tongue, and vulva. The method employed is to burn away as much as possible of the growth and then thoroughly to irradiate the surrounding tissues and the neighbouring lymphatic glands. Dr. Burrows states that after the main mass of growth has been excised by diathermy from the breast, he inserts radium tubes along the lymphatic channels into the axilla, with excellent results. He does not describe his technique for carrying out what must necessarily be a difficult procedure. We learn from the report that good results have followed the treatment of carcinoma of the tongue by the burying of unscreened emanation tubes into the growth, but no details are given as to the form taken by these tubes. Are they minute glass "seeds" which are inserted and then left indefinitely, or are they tubes which are removed after a certain period? Those who follow this procedure would need to know the strength of their radio-activity and the hours of exposure as well as something of the method by which the necessary millicurie dosage for any case is arrived at. No one will disagree with Dr. Burrows's statement that radium gives almost perfect results in the treatment of rodent ulcers, where there is no involvement of bone and cartilage; when this condition is present, he has found that the excision of the edges of the ulcer by diathermy followed by deep electro-coagulation was good procedure. The report discusses the important question of the treatment of carcinoma of the body of the uterus, for which condition operation is still considered best. For uterine hæmorrhage, other than that caused by carcinoma, Dr. Burrows aims at reducing but not completely suppressing menstruation. He reports several cases amongst his patients at the Institute of normal childbirth subsequent to radium treatment for menorrhagia. A young woman after five years of childless married life and a longer period of menorrhagia was treated with radium, regained normal menstruation, and over a year later gave birth to a healthy child. Whether the Manchester Institute is employing the methods now so strongly urged in Paris, Brussels, and elsewhere of treating carcinoma by small amounts of radium for very prolonged periods is not stated. Many practitioners now possess small amounts of the precious element, and it is to institutions such as this that they naturally look to for help and practical instruction in its use. In future reports they would welcome fuller details of dosage and screening technique.

VACCINES IN THE TREATMENT OF TYPHOID AND PARATYPHOID FEVER.

THANKS in part to its good water-supply and close supervision of its milk trade, Copenhagen is remarkably free from enteric fevers, and in 1922 only 19 cases of typhoid and paratyphoid fever were notified. This state of affairs is an eloquent tribute to preventive hygiene, and doubtless prevention alone will some day stamp out these diseases. In the meantime, we have to consider the best measures for treating these ailments as well as preventing them, and in this connexion a most encouraging paper has recently been published by Prof. Valdemar Bie,[1] of the Blegdams Hospital, in Denmark. He has given a typhoid vaccine to 13 cases of typhoid fever and six of paratyphoid B fever. The vaccine was made from an agar culture of typhoid bacilli, and was in most cases given by intramuscular injection, the doses on five successive days being 100, 200, 400, 700, and 1000 million typhoid bacilli. The diagnosis in the cases thus treated was confirmed by a positive Widal reaction or by the culture of typhoid or paratyphoid bacilli from the blood or fæces. The numerous charts showing the action of the vaccine on the temperature bring out one interesting point: whether the fifth and last injection was given as early as the thirteenth or as late as the fortieth day of the disease, it was almost invariably followed in a day or two by a fairly rapid fall of the temperature by lysis to normal. Only in one case did the temperature fall by crisis on the day following the last injection, and such a fall was not considered desirable on account of the risk of serious collapse, such as was often seen during the war in Germany and Austria as a sequel to intravenous injections of typhoid vaccine in cases of typhoid fever. The conversion in most of Prof. Bie's cases of a high, continuous temperature to one that fell by rapid lysis was associated with other signs of improvement, such as a return of the appetite and the cessation of diarrhœa. There was only one death in this series of cases, and in this case the patient was very weak and already suffering from pneumonia when the first injection was given on the twenty-second day of the disease. In another case the patient's recovery did not seem to depend on the vaccine, no response to which could be observed. The action of the vaccine being effective in both the typhoid and paratyphoid groups, it could not be regarded as specific, and Prof. Bie suspects that these cases were illustrations of the efficiency of non-specific protein therapy. Recently he has been treating cases of typhoid and paratyphoid fever with intramuscular injections of a staphylococcal vaccine, and the results were as good as with his typhoid vaccine. The success of prophylactic vaccination against typhoid and paratyphoid fever depending essentially on the specific properties of the vaccine, it is curious to find the specificity of a vaccine playing such an unimportant part when it comes to treating an already established infectious disease.

HÆMATOPORPHYRIN AS A SENSITISER.

THAT media of various kinds can be greatly sensitised by the addition of very small amounts of certain pigments has long been known to photographers—e.g., sensitising a photographic emulsion film by the addition of minute traces of eosin. Amongst hæmoglobin derivatives, the researches of Hausmann, Meyer-Betz, and others have increased our knowledge of the photo-dynamic action of hæmatoporphyrin, which acts as a remarkable sensitiser. A small quantity of this substance injected into white guinea-pigs renders them so sensitive that they die from exposure to light. Meyer-Betz injected into himself very small quantities of hæmatoporphyrin and after exposing himself to very moderate light made himself very ill. This sensitisation to light opens up an entirely new field in therapeutics. As a further development in this direction is the work of E. C. van Leersum on the influence of hæmatoporphyrin on the deposition of lime salts in the bodies of rachitic rats.[1] Rats were rendered rachitic experimentally by feeding them on a diet composed of gluten, maize, gelatin, common salt, and calcium carbonate after the manner adopted by McCollum. The animals presented all the well-known phenomena of experimental rickets—swelling and diminished consistence of the osteoid tissue of the long bones, the rosary in the ribs, and the characteristic changes between the epiphysis and shafts of the long bones, together with the imperfect deposition of lime salts in the osseous tissue. These rachitic rats were treated at intervals by injecting subcutaneously 3–10 mg. of hæmatoporphyrin in an alkaline solution. The results on these animals were compared with numerous controls, both by X ray examination during life and microscopic examination after death, as well as by a study of amputated hind legs before the hæmatoporphyrin injection was begun. Various tests were made to determine the influence of hæmatoporphyrin on the deposition of lime salts. The favourable action of the pigment both on albino and parti-coloured rats suffering from experimental rickets was confirmed. It is suggested that this substance produces a special sensibility for those light rays where photo-dynamic action in comparison with the ultra-violet rays is small and which are ineffective against rickets, that there is a sensitising action of hæmatoporphyrin during the whole experiment while the animals are confined in a badly lighted room.

TOXIC EFFECTS OF LOCAL ANÆSTHETICS.

FOLLOWING on the discussion which recently took place in the Section of Therapeutics of the Royal Society of Medicine on the dangers arising from the simultaneous use of adrenalin and novocaine, a report of an investigation instituted by the American Medical Association into the occurrence of accidents from the use of local anæsthetics, which has just been published [2] is of some interest. A committee, on which all branches of medicine and surgery were represented, collected from replies to a questionnaire sent to members of the American Medical Association no less than 43 cases of deaths following local anæsthetics, all of which occurred in the course of three years. The findings and recommendations of the report are based on a careful analysis of these cases, and they bring out several points of importance. The majority of the deaths (26) were due to cocaine; butyn and apothesin were each responsible in four cases, and alypin, novocaine, and stovaine each in one or two. The symptoms produced were in all cases very similar, consisting in dyspnœa and arrest of respiration within a few minutes of the administration of the anæsthetic. The only useful method of treatment, in the opinion of the committee, is artificial respiration, perhaps accompanied by massage of the heart, while the use of morphine or adrenalin is definitely contra-indicated. The cause of the accidents was in almost all cases the use of unnecessarily large amounts of the anæsthetic, so that while the committee are aware of the possibility of individual idiosyncrasy playing a part in such cases, and of the existence of evidence suggesting that the simultaneous use of adrenalin heightens the toxicity of local anæsthetics, they are convinced that greater care in the matter of dosage and in the observance of certain rules will largely eradicate accidents. Thus it was striking that very few serious accidents have occurred in large hospitals. They recommend (1) that cocaine should not be injected into the submucous tissue or subcutaneously; (2) that cocaine paste should never be used; (3) that local anæsthetics should not be injected into the urethra where trauma or stricture exists; (4) that the following concentrations be regarded as safe: cocaine, in the mouth and epipharynx, 5 per cent.; in the nose, not over 10 per cent., and in total amounts of from 10 to 15 minims containing 1 to 1·5 gr.; in the eye, not over 5 per cent.; in the larynx and bronchi, not over 20 per cent. (preferably 10 per cent. in two applications), and not over 15 minims total. Novocaine should not be used in greater concentration than 1 per cent.; apothesin, not greater than 2 per cent. Butyn should not be used for injection. With reference to the use of adrenalin, in conjunction with cocaine, not more than 10 minims of 1 : 10,000 are permissible, and in conjunction with novocaine not more than 15 minims of 1 : 1000. The committee state that the result of their investigation has convinced them that accidents from the incautious use of local anæsthetics are common in medical and dental practice in America. Their report, written as it is with judgment and care, should be of assistance in lessening such occurrences.

MALARIA AND RHEUMATISM.

DR. L. Lichtenstein,[1] of Bad Pistyan, remarks that it is of historical interest that at a time when malaria was supposed to be due to miasms acute articular rheumatism was also attributed to the same cause. Some writers, such as Haygarth, regarded acute articular rheumatism as a masked form of intermittent fever. This view was based on the tendency of both diseases to arise in low-lying damp localities and in certain climates to last for a very long time, and to be cured by certain specifics. Shooting pains in the muscles, dull pains in the knees, tenderness of the tibiæ, and aching in the sacral and lumbar vertebræ have long been known to be frequent accompaniments of an acute attack of malaria, but only a few cases have hitherto been recorded of malaria being complicated by polyarthritis. According to Fayrer, articular rheumatism is a frequent complication of malaria in Indian natives, but is not, like ordinary rheumatism, followed by endocarditis. Dr. Lichtenstein's experience is based on 21 cases of malaria complicated by polyarthritis. He divides the cases into two groups, the first comprising three cases in which polyarthritis developed in the acute stage of malaria, and the second group consisting of 18 cases in which it occurred in convalescence. In the first group the polyarthritis appeared on the fourteenth day and was not affected either by quinine or salicylates. In the second group, which consisted of 10 cases of benign tertian, 3 of quartan, and 5 of malignant tertian, the signs of acute articular rheumatism developed from two to six weeks after the last attack of malaria. In six cases the polyarthritis was afebrile and in 12 accompanied by fever, which was sometimes high or characterised by irregular remissions or intermissions. In almost all cases the knee-joints were affected either alone or in association with the shoulder- and ankle-joints. The fingers and toes were never involved. The blood showed no malarial parasites during the presence of polyarthritis. Quinine and salicyl preparations which were usually combined caused some improvement, but had no remarkable effect. The course of the disease was usually protracted, and more or less severe changes persisted in the joints until they were relieved by thermal treatment. Dr. Lichtenstein is of opinion that the polyarthritis is of malarial origin owing to the date of its occurrence, and also because no organ in the body is unaffected by malarial toxins. The fact that the complication does not yield to quinine or salicyl preparations is no objection to this view, as there are plenty of cases of malaria that do not react to quinine and of acute articular rheumatism that are not affected by salicylates. There is, therefore, no justification for denying the existence of a malarial rheumatism.

THE INCUBATION PERIOD OF GENERAL PARALYSIS.

THE factors determining the outbreak of general paralysis are still so imperfectly known that a statistical investigation of this subject by Dr. Fritz Wiesel [1] is opportune. It has been suggested that the outbreak of this disease may be influenced by the behaviour of the original syphilitic infection—e.g., by its response to specific treatment, and that such factors as heredity—i.e., a family history of insanity and diseases of the central nervous system—degenerative stigmata, alcoholism, injuries to the head, influenza, over-exertion, and psychic strain may play an important part in hastening, or even determining, an outbreak of general paralysis. Another teaching, associated with the name of Dr. R. Stern, is to the effect that persons with a fragile build are predisposed to tabes, while fat, muscular, and robust persons are predisposed to general paralysis. Dr. Wiesel's researches provide little support for these ingenious correlations. His material consisted of 188 cases of general paralysis observed in various Swedish hospitals in the period 1907–20. In all these cases information was obtained as to the date when syphilis was contracted. In two cases the incubation period of the general paralysis was as short as two years; the longest incubation period was 39 years. Most of the cases developed from 10 to 20 years after infection, but there were as many as 51 cases, or 27 per cent. of the total, in which the incubation period was longer than 20 years. In 36 cases, or 19 per cent. of the total, it was under 10 years. The average length of the latent period was 16·6 years. As for the many different factors which are supposed to determine the outbreak of general paralysis, Dr. Wiesel could find none, with the possible exception of bodily over-exertion, psychic injuries, and influenza, which bore more than an incidental relation to the development of the disease. A record of relapses of syphilis of the skin and mucous membranes could not be correlated with any peculiarities in the subsequent general paralysis or its incubation period, and the age of the patient when syphilis was contracted, the patient's sex, and the vigour with which mercurial treatment had been pushed, were also factors the bearing of which on the development of the paralysis was obscure. But it seemed that when the incubation period was short the paralysis often proved fatal in a comparatively short time. In nine cases, in which the incubation period was only two to five years, the average duration of the paralysis, from its outbreak to death, was between 12 and 13 months. Though most of the findings in this paper are in a sense negative, it has served a useful purpose in clearing the ground for a careful and systematic study of a disease whose many natural riddles have been unnecessarily complicated by physicians with a flair for speculation rather than with a capacity for painstaking observation.

THE INNERVATION OF DENTINE.

THAT the dentine of the teeth is sensitive is a clinical fact familiar to all who have sat in the dentist's chair. The actual cause of this sensitiveness has been the subject of much speculation and investigation, until the discoveries of Howard Mummery in 1912 and succeeding years showed that the nerves of the dental pulp terminated in arborisations round a layer of nerve cells close to the margin of the pulp. The axons of these cells pass into the tubules of the dentine and have been traced as far as the junction of the dentine and enamel. Recently Mr. Mummery has shown that the nerves of the pulp in their course give off vaso-motor fibres to the arteries. In a paper read before the Odontological Section of the Royal Society of Medicine on April 28th he discussed the present state of our knowledge on this subject, and in order to make conviction more complete showed the original sections under the microscope. Sections of such delicacy as these are easily damaged, but there is no doubt that to those used to microscopical work the examination of the sections themselves carries with it a satisfaction and conviction lacking in drawings or micro-photographs. Though the majority of competent histologists have long since accepted the accuracy of Mr. Mummery's work, an occasional note of scepticism has been heard. We imagine that doubt can be no longer possible to those who were present at the reading of the paper and had the opportunity of examining for themselves the original preparations, and, with finger on fine adjustment, of tracing the course of the delicate neuro-fibrils from the pulp into the dentinal tubes.

UNUSUAL ACCIDENTS WITH ANÆSTHETICS.

Two accidents, both unusual but neither of them unprecedented, have recently been reported in connexion with two of the safest anæsthetics—nitrous oxide and ether. They point the moral that in handling narcotic drugs—even those least easily associated with danger—care must be detailed and unremittent. The accident with ether resulted in severe burns to two individuals in the operating theatre. According to the press account the anæsthetic had been successfully administered *when a spark* from some electrical apparatus exploded a bottle of ether with great force. The ether burst into flames and the theatre was set on fire. This account is probably faulty in detail, for it is not easy to conceive of a closed bottle of ether being exploded by an electric spark. If the bottle were spilt, then, of course, the mixture of ether vapour and air which would be present might easily be ignited by an electric spark and might burst into flame with a detonation. One case has already been recorded in which vapour of ether and oxygen was thus "exploded" by the small electric globe of a laryngoscope. And on several occasions ether has burst into flame when a mixture of its vapour and air has been allowed to meet an open fire or a gas jet. In the case we are referring to, it is conceivable that the bottle of ether was in some place where it became hot enough for the ether to boil and burst the bounds of the bottle. Then it could have been ignited by the electric spark. Ether boils at a temperature of 96° F., and it is easily conceivable that this temperature might have been found in the immediate neighbourhood of a steriliser or heating apparatus. The other accident was unhappily fatal. It befell a student who was in the habit of trying the effect of nitrous oxide on himself. No solitary experiment should ever be made with a narcotic, even so apparently safe a one as nitrous oxide. For if unconsciousness supervene mechanical circumstances may render recovery impossible in the absence of immediate aid. This is probably the explanation of the rare deaths through nitrous oxide taken in solitude. When unconsciousness came through inhaling the gas the unfortunate experimenter, instead of letting go the apparatus and falling away from it, when recovery would rapidly ensue in all probability, most likely fell in such a position that his mouth and nose were pressed into the face-piece, resulting in fatal asphyxia. A similar accident was reported not long ago, when the position in which the body was found in relation to the apparatus pointed unmistakably to this explanation.

THE DRINKING OF WATERS.

MEDICAL hydrology first began to receive serious consideration for the treatment of disease in this country more than two centuries ago; it is now slowly gaining a place in scientific medicine and becoming a recognised part of therapeutics. As regards both the internal and external application of natural mineral waters the indications for treatment have become more precise and their method of application more exact. No doubt the indiscriminate use of hydro-therapeutic measures, in which the choice of spa was often decided less by the suitability of its waters to any particular case than by the personal tastes of the patient, has delayed hydrology from taking its proper place in the esteem of the medical profession. The amenities of spa life, both social and climatic, are many—some of them are set forth in the notes on French Spas which appear on p. 1037—and exercise a beneficent influence irrespective of the water cure, but in our time it is only when combined with scientific application of the waters that they can command the whole-hearted approval of the medical world. The drinking of water, apart from the consideration of its specific mineral content, requires in many disease conditions to be carefully regulated to the needs of each particular case, and in our columns this week Dr. P. L. Violle, of the Institute of Hydrology in Paris, gives an account of the physiological tests he employs to determine the fate of liquids ingested by patients suffering from cardiac, renal, and cardio-renal affections. Such knowledge, as he points out, is indispensable in establishing the conditions under which absorption, diffusion, and elimination may be most efficiently accomplished, and in consequence how the dosage and nature of the liquids may be regulated. From the results of his fractional diuresis tests Dr. Violle draws definite conclusions for the regulation of liquid intake in certain pathological states. It is work of this nature carried out in the laboratory which is needed to supplement the existing knowledge of the therapeutic properties of spa waters in order that the maximum benefit to the patient may be obtained. Hydrology is but little studied in this country, although some consistent efforts are being made to supply the deficiency. In our news columns this week will be found a brief account of the second course of study under the auspices of London University, this time with practical demonstrations at Bath. During the coming week-end the new natural mineral water baths will be opened at Buxton. There is admirable equipment at our home spas for the study of hydrology, as it has been studied at many places on the continent, and Dr. Violle's paper shows one direction in which good work can be done.

THE summer session of the General Medical Council will commence at 2 P.M. on Tuesday, May 27th, when the President, Sir Donald MacAlister, will take the chair and give an address. The Council will continue to sit from day to day until the termination of their business.

THE Royal College of Physicians of London decided last week to discontinue the language test at the examination for the Membership. This test consisted in rendering into English two passages, one in Latin or Greek, the other in French or German. While the test acted as a deterrent to some otherwise suitable candidates, it could hardly be seriously regarded as evidence of scholarship, and therefore it has been discontinued rightly. Credit will still be given to those who desire to show real knowledge of languages, ancient or modern.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LXXI.

THE TREATMENT OF RENAL TUBERCULOSIS.

IT may be stated that in approximately 95 per cent. of all cases in which pus and tubercle bacilli are found in the urine the infection is renal in origin. The remaining 5 per cent. are accounted for by an ascending infection of the prostate and bladder in genital tuberculosis, by a process of elimination in miliary infections, and very rarely by primary tuberculosis of the bladder.

Before a definite line of treatment can be initiated a most careful investigation of the urinary tract must be made in order to fix the site and estimate the degree of infection present. The points to be elicited are as follows:—

(*a*) Abdominal examination may reveal an enlargement of one or other kidney with local tenderness; such symptoms may be due to disease, but it must always be remembered that the healthy kidney may have enlarged owing to more work having been thrown on it.

(*b*) Rectal examination often gives information of the extent of the disease, the points to be specially investigated being thickening of the ureters, and, in the male, involvement of the prostate.

(*c*) In the male careful examination of the external genitals should be made to disclose the presence of a primary or secondary epididymitis.

(*d*) Cystoscopic examination is essential in order to determine the presence of a badder infection, the location of the renal infection, and if one kidney alone appears to be infected the integrity and functions of the other kidney must be determined by ureteral catheterisation.

(*e*) A careful general examination of the patient must be made for the presence of active tuberculosis elsewhere than in the urinary tract.

Classification of Cases.

From the point of view of treatment cases may be classified as follows:—1. Unilateral renal infection, the other kidney being healthy, and with no infection of the lower urinary tract. 2. Unilateral infection with (*a*) secondary cystitis; (*b*) in the male, secondary infection of the epididymis on the same side; (*c*) associated nephritis or other non-tuberculous infection of the other kidney; and (*d*) associated active tuberculosis in some other part of the body. 3. Bilateral renal infection with or without secondary infection of the lower urinary tract or associated infection in other parts of the body.

Uncomplicated Unilateral Infection.—In Class 1, provided that the uninfected kidney is healthy and its excretory power is satisfactory, removal of the tuberculous kidney by lumbar nephrectomy should be performed, together with as much of the ureter as is possible through the same incision, if this shows evidence of infection at the time of operation.

Unilateral Nephritis with Complications.—In Class 2 (*a*) where there is a marked degree of bladder infection and irritability adequate examination often cannot be made until the bladder condition has improved. For this purpose complete rest in bed, together with tuberculin in small doses on the lines described below in the treatment of bilateral infections, should be tried. After six to eight weeks cystoscopy and ureteral catheterisation can usually be carried out under general or spinal anæsthesia, and, on proof having been obtained that the infection is unilateral, treatment is carried out as in the first class with, in addition, removal of the whole length of the ureter, if this is heavily infected, a separate incision being made for the lower part if necessary.

(*b*) When a unilateral infection is complicated by tuberculosis of the epididymis on the same side by spread of the infection from the ureter to the vas, the initial treatment is identical with that indicated above—i.e., removal of the tuberculous kidney and ureter. If the operation is followed by adequate after-treatment by tuberculin, &c., as given below, in the majority of cases the lesion in the epididymis will heal. Castration should be reserved for cases in which extensive destruction of the testis and epididymis has occurred from caseation.

(*c*) In a certain number of cases of unilateral renal tuberculosis the urine from the uninfected kidney is found to contain albumin and possibly casts—i.e., a condition of nephritis is present. A careful investigation of the renal functions as a whole by blood-urea examination, and of the uninfected kidney by colorimetric and other tests should be carried out before operation is undertaken. Each case has to be judged on its merits, and no hard-and-fast rule can be laid down as to operability if this complication is present. In cases of doubt sanatorium treatment, together with tuberculin, will often improve the patient sufficiently to allow a nephrectomy to be performed. In a number of cases nephrectomy is followed by a complete disappearance of the signs of nephritis which were toxic in origin.

(*d*) Associated tuberculosis in some other part of the body is no bar to operation in unilateral infections, provided such lesion is quiescent or healed. Active pulmonary tuberculosis must be considered as a contra-indication to operation, and the risks of lighting up the infection as a result of anæsthesia must always be remembered in quiescent lung lesions.

After-treatment of Cases Treated by Operation.

A fortnight after operation, while the patient is still in bed, a course of tuberculin injections should be commenced. The initial dose of tuberculin (B.E.) depends to a certain extent on the severity of the infection, on the general condition of the patient, and on the presence of associated tuberculous lesions. As a rule in an uncomplicated case the first dose may safely be 1/20,000 mg.; if no reaction results, the dose is increased each week until a maximum dose of 1/100 mg. is reached in about 12 weeks. In cases complicated by other tuberculous lesions the doses are necessarily smaller, and in any type of case the dose should be regulated so as to produce the minimal amount of reaction. The doses should be given at the same time of day, and a four-hourly chart should be kept for 36 hours after each injection to check the reaction.

As a rule, in an uncomplicated case, the injections should be continued for six months, longer periods being necessary in more severe conditions; during the later stages of treatment the fact that injections are being given is no bar to the patient resuming his ordinary occupation. Regular examinations of catheter specimens of urine should be made during convalescence, and treatment by tuberculin should be continued for at least two months after tubercle bacilli and pus have disappeared from the urine.

Apart from treatment by tuberculin, the general after-treatment of these cases is similar to that indicated for any other case of surgical tuberculosis, with the exception that it is generally advisable for the patient to live in a rather milder climate than that usually recommended. In this country the south and south-west are preferable to the east and south-east coasts, and extremes of temperature are always to be avoided. The duration of convalescent treatment depends on the severity of the initial infection, but it is advisable to regard three months as a minimum, after which, in an uncomplicated case, the patient may resume his ordinary avocation.

As a rule, steady improvement follows treatment on these lines, the patient loses all symptoms, gains in weight, and the bladder symptoms rapidly disappear. Occasionally persistent bladder irritability continues, when the methods indicated later under the treatment of bilateral infections should be tried; it is necessary to emphasise that on no account should the bladder be irrigated, as this does no good, and may do much harm owing to the risk of a secondary pyogenic infection.

Prognosis.—The operation mortality in nephrectomy for tuberculosis of the kidney is with modern conditions very low, being under 1 per cent. The end-results, as shown by statistics published in this country and abroad, and from personal experience, are extremely satisfactory; in uncomplicated cases a permanent cure can be expected in 85 per cent. of cases after operation.

Treatment of Bilateral Infections.

In Class 3, where the infection is definitely bilateral, operative treatment in nearly every instance is impracticable, apart from such relief as may be obtained by the aspiration of a large tuberculous pyonephrosis or similar palliative treatment. The removal of the most seriously affected kidney has been advocated in the hopes of prolonging the patient's life, but is rarely, if ever, justifiable. The only hope of improvement lies in general treatment, together with a prolonged course of tuberculin injections.

General treatment is best carried out on sanatorium lines, the patient remaining at complete rest for the first three months at least. Diet need not be modified with the exception of some limitation of nitrogenous intake in severe cases. Extra fatty foods are essential and cod-liver oil with malt in large doses is always useful. The chief symptom which requires treatment is the frequent painful micturition which is so commonly marked in these cases. Local treatment of the bladder by irrigation or instillation is to be avoided, as it does little or no good, and may be the cause of a secondary pyogenic infection. Hexamine and its derivatives are of little value and often increase the bladder discomfort. On the whole, the following prescriptions, which may be alternated from time to time, seem to give most relief:—

(*a*)

℞ Tinct. hyoscyami .. ♏xx.
Liq. opii sedativi .. .. ♏ii.
Potassii citratis .. .. gr. xx.
Aquam chloroformi .. ad ℥i.

One ounce to be taken three times a day after meals.

(*b*)

℞ Ol. santali, ♏xx., in gelatin capsules.

One capsule to be taken three times a day after meals.

(*c*)

℞ Methylene-blue, gr. ii., in cachet.

One cachet to be taken three times a day after meals.

(*d*) The introduction of a suppository containing morphine hydrochloride, gr. ¼, and ext. belladonnæ alcoholic, gr. ½, into the rectum at night will often give relief from the nocturnal frequency which is so distressing.

Tuberculin Treatment.—After three weeks' complete rest in bed injections of tuberculin (B.E.) should be started. The initial dose depends on the severity of the infection and the presence of associated tuberculous lesions; it should always be very small, and as a rule 1/500,000 mg. is suitable. Doses should be given at four-day intervals at first in very gradually increasing strengths until 1/50,000 mg. is reached, then at weekly intervals until 1/100 mg. as a maximum is being given. As a rule, the time taken to raise the dose to the maximum is six months, and if this plan is carried out no reaction should be caused; any definite reaction is an indication for an immediate reduction of the dose. Treatment by tuberculin, if definite improvement is obtained, should be continued for at least a year, and in many cases may be continued for a much longer period.

Prognosis.—Bilateral renal tuberculosis is rightly considered to be a very fatal disease, especially when occurring in children and young adults, but from experience gained during the last five years it has been found that with prolonged and careful sanatorium and tuberculin treatment in a certain number of cases there is a chance of prolonging life, and in a few cases complete cessation of symptoms and disappearance of tubercle bacilli and pus from the urine have resulted.

CERTAIN
OBSERVATIONS ON MALARIA MADE DURING TREATMENT OF GENERAL PARALYSIS.

Abstracted from a Communication made on May 15th to the Royal Society of Tropical Medicine and Hygiene, which will appear in full in the Transactions of the Society, Vol. XVIII., Nos. 1 and 2.

BY WARRINGTON YORKE, M.D., CH.B. LIVERP.,
PROFESSOR OF PARASITOLOGY, UNIVERSITY OF LIVERPOOL;
AND
J. W. S. MACFIE, D.SC., M.B., CH.B. EDIN.,
D.T.M. LIVERP.

Infections Produced by Inoculation.

Quartan Malaria.—On July 21st, 1922, two cases of general paralysis were inoculated from a case of quartan malaria contracted in West Africa. Both cases became infected, parasites being found in the peripheral blood within three weeks, and from these cases two others were successfully inoculated. All four cases were treated after the fever had lasted from three to five weeks with quinine in solution, gr. 30 orally, daily for two months; parasites disappeared from their blood in from four to seven days, the fever speedily subsided and no relapse, either febrile or parasitic, occurred.

On Nov. 25th, 1923, two other cases of general paralysis were inoculated with quartan parasites from an old-standing, naturally infected patient. No sign of infection was apparent up to Jan. 3rd, 1924, and it was assumed that the inoculations had failed, and one of the two patients was reinfected by the bites of *Anopheles maculipennis* infected with *Plasmodium vivax.* This case is of interest in connexion with the unicity theory of the malaria parasites, and will be referred to later.

Malignant Tertian Malaria.—One case inoculated with the blood from a patient suffering from malignant tertian malaria developed an infection of a fulminating character and the disease terminated fatally.

Simple Tertian Malaria.—As it was considered more desirable to work with simple tertian malaria, no attempt was made to carry on the strain of quartan or malignant tertian parasites. On Sept. 8th, 1922, a case of general paralysis was inoculated with simple tertian malaria. From this patient a long chain of cases of general paralysis has been infected with the result that during the last 20 months the strain has been transmitted by direct subcutaneous inoculation through 23 passages comprising 70 cases; of these 70 cases, five failed to become infected at the first inoculation. In addition to the cases in this chain, 28 other cases were inoculated either from naturally infected malaria patients or from second inoculation passages, and of these four failed to become infected at the first inoculation. The incubation period showed considerable variations, but was for the most part between 8 and 15 days. In four of the 98 cases the malarial infection underwent spontaneous cure in from 5 to 14 days; no relapse occurred. Of 61 cases treated with quinine orally for two to four days, practically all with quinine in solution, gr. 30, on each of three consecutive days, only one relapsed during an observation period which varied from 4 to 18 months, except in a very few cases in which it was between 2 and 4 months. Of 13 cases treated with the usual three-day course of quinine, gr. 30, on each of three consecutive days, and subsequently with two or three injections of small doses of novarsenobillon, only one relapsed during an observation period varying from 5 to 12 months. One case treated by two small doses of novarsenobillon only has not relapsed during an observation period of eight months.

A number of observations were made in order to ascertain whether by the administration of small daily doses of quinine for a short period before, and after, the inoculation of virulent blood it was possible to obtain a modified infection which might prove of equal value to the ordinary severe infection in the treatment of general paralysis. In eight cases to whom an oral dose of 10 gr. of quinine was given for varying periods before and after inoculation the development of infection was prevented during an observation period varying from 5 weeks to 4 months.

Infections Produced by Mosquitoes.

In certain cases it was considered desirable to infect patients by the bite of mosquitoes instead of by direct inoculation of infective blood. The mosquitoes used were mainly *A. maculipennis* infected with *P. vivax* by feeding on patients. The intensity of infection observed in mosquitoes fed on the same patient at the same time was fairly constant, but the degree of infection varied considerably among different batches of mosquitoes. It seems probable that these differences in intensity of infection are due not to any variations in the mosquito, but rather to the state of the patient's blood at the time the insects fed. When blood films made at the time of feeding showed the presence of many large and apparently full-grown gametocytes, the resulting infection in the mosquitoes was intense and a large proportion was found to be infected. The feeding of a mosquito which on dissection immediately after the meal was found to contain sporozoites in its salivary glands, in our experience, never failed to result in infection of the patient. However, the mosquitoes were always used for producing infection within a period of from 12 to 30 days after the infecting feed. We did not attempt to investigate the question how long they remained infective or how many persons it was possible by successive feeds to infect from one mosquito, but it was observed on the few occasions where an infective mosquito was fed successively (within the periods mentioned) on three or four patients infection always resulted. Of 41 cases, 39 were treated with the usual short course of quinine—i.e., gr. 30 in solution on each of three consecutive days. Six died shortly after treatment without parasites in the blood, and two about a month after treatment without having relapsed. Of the 31 cases who survived, four (13 per cent.) have relapsed within an observation period varying from two to six months. The other two cases were treated with several small doses of novarsenobillon and both of them relapsed.

Reference has already been made to the prophylactic action of quinine in inoculated malaria. It was decided to repeat these observations with the mosquito-borne strain, not only for the reasons given previously, but also because anopheles capable of spreading malaria are known to exist in the grounds of many of the mental hospitals in this country, and it seemed desirable to ascertain whether, if necessary, the inmates of the mental hospitals and the general public in the neighbourhood could be protected against accidental infection by quinine administered as a prophylactic.

It was found that when even small daily doses (5 gr.) were continued for two to six weeks after inoculation protection was given, but even large doses given before inoculation failed to protect unless they were continued for a considerable time after inoculation.

Unicity Hypothesis of Malaria Parasites.

Even up to the present time a number of authors adhere to the view that there is only a single species of malaria parasite found in man. The following observations made in the course of this work appear to render the unicity hypothesis untenable. 1. In six patients inoculated between July and November with *P. malariæ* only forms typical of this species appeared in the blood. 2. In one patient inoculated in July with *P. falciparum* only forms typical of this species appeared in the blood. 3. In 98 patients inoculated at all periods of the year with *P. vivax* only forms typical of this species appeared in the blood. 4. In 41 patients infected between September, 1923, and April, 1924, by the bites of *A. maculipennis* or *A. bifurcatus* infected with *P. vivax*, only forms typical of this species appeared in the blood. This observation appears to us to be particularly important in view of the statement, frequently to be found in French literature, that primary infections are malignant tertian. 5. Finally, as already recorded, a case was inoculated with *P. malariæ* from a naturally infected patient on Nov. 25th, 1923, and as he had not shown parasites in his blood or exhibited any symptoms of malaria by Jan. 3rd, 1924, was subjected to the bites of mosquitoes infected with *P. vivax*. This patient showed *P. malariæ* for the first time in his blood on Jan. 8th, and *P. vivax* for the first time on Jan. 18th; both parasites persisted in the blood up to the time of treatment.

Effect of Numerous Direct Passages of P. vivax Through Man.

It is now well recognised that many trypanosomes pathogenic to man and stock undergo a marked increase in virulence to certain species of laboratory animals when maintained in them for long periods by direct inoculation from one host to another. In some cases—e.g., *Trypanosome brucci* vel *T. rhodesiense*, this alteration of virulence is attended by certain morphological changes. It is important, however, to note that such changes do not occur in the early passages, but apparently take place only after the strain has undergone a certain number of direct passages through the vertebrate host. It is therefore of considerable interest and importance to inquire whether the prolonged sojourn of *P. vivax* in the human host, comprising 23 direct passages from man to man without the intervention of the insect intermediary during a period of nearly two years, has had any influence on the parasites or on the type of infection which it produces.

Comparisons between the types of infection, temperature charts, and clinical signs in patients infected early and those infected after several passages indicate that the strain had undergone no increase in virulence during its direct passage from man to man through 23 generations, nor does the morphology of the parasite appear to undergo any change after many passages.

Susceptibility of Induced Malaria to Treatment.

The observations of previous writers, that general paralytics who had been infected with malaria by inoculation were easily cured by comparatively short courses of treatment with quinine and salvarsan or with quinine alone, have been confirmed by us. On contrasting the results of treatment of inoculated cases with those obtained in the treatment of simple tertian malaria during the war and in ordinary practice, one cannot fail to be impressed by the striking difference, especially in the percentage of relapses.

Various hypotheses have been advanced to explain the remarkable sensitiveness of the *inoculation-strain* to quinine treatment. It appears to us that the true explanation of the success of treatment in these induced infections is to be sought in the fact that we are here concerned with the early treatment of disease, or, in other words, with the treatment of primary infections, and not, as in the war or as frequently in practice, with old-standing relapse cases.

The Mechanism by which Cure is Obtained in Malaria.

In endeavouring to explain why a cure is sometimes effected and sometimes not, we commence with the assumption that no form of quinine therapy per se ever destroys all the malaria parasites in the human body. In the treatment of malaria, the train of events is, in our opinion, as follows. Quinine given to a patient whose blood contains numerous malaria parasites invariably destroys directly, or more probably indirectly, large numbers, but not all of the parasites, thus setting free a considerable quantity of soluble antigen. The antigen provokes by stimulation of the host's tissues the formation of immune-body. The immune-body, if present in sufficient amount, destroys the remaining parasites, thus resulting in sterilisation of the infection and the cure of the patient. For a cure to be obtained, this hypothesis demands, first, the setting free of a considerable quantity of soluble antigen by the destruction of a large number of parasites, and, secondly, a capacity on the part of the host to respond to the antigen by the formation of a sufficient quantity of immune-body. If for any reason either of these two requirements is not satisfied, the infection is not completely sterilised and a relapse occurs. With regard to the first of these two requirements, we have long been impressed with the fact that the administration of quinine when the blood contains numerous parasites is more efficacious than its administration when the blood is free from parasites. The second requirement for the production of a cure is that the cells or tissues of the host shall be able, in response to the antigen stimulus, to produce a sufficient quantity of immune-body. That the human host exhibits a certain degree of natural immunity to malarial infection and that this is capable of being increased in response to the proper stimulus there can be little doubt.

There is, in our opinion, a considerable mass of evidence indicating that man exhibits some degree of immunity to malaria and that this is capable of being increased in response to the proper stimulus. His natural immunity is but slight, and in the vast majority of cases insufficient to prevent the development of the infection; in patients who have recovered, either spontaneously or after medication, from an acute attack of the infection the immunity may be increased to such an extent that it may be impossible to reinfect for various periods, which are probably much shorter in the European than in the native; and finally, in cases where the symptoms have subsided spontaneously, without the complete disappearance of parasites from the blood, reinfection by the feeding of infective mosquitoes does not result in an exacerbation of fever. The immunity is, however, relatively slight, and there is evidence that the malaria parasites readily develop an immune-body resistance. It is important to note that immunity developed against one species of plasmodium does not confer a similar protection against the other species.

We consider that there exists considerable evidence in support of the hypothesis that the essential factor for the production of cures in malaria is the capacity of the host to produce immune-body in response to the antigen formation resulting from the destruction of a considerable number of parasites by a medicament. When for any reason the host is unable to produce immune-body in sufficient amount, sterilisation does not take place and a relapse occurs. We surmise that certain individuals are unable to produce a sufficiency of immune-body to sterilise the malaria infection owing to ill-health at the time of infection and treatment or possibly owing to a personal idiosyncrasy, and that these are the patients which develop eventually into chronic relapse cases. The immune-body produced in such cases is insufficient to destroy all the parasites which have escaped the action of the quinine; the parasites which persist gradually acquire an immune-body resistance, so that the relapse strain, although reacting to quinine as usual, is not completely destroyed by immune-body.

Quinine Prophylaxis.

Observations on the value of quinine prophylaxis showed that administration of the drug before infection is useless, that its administration must be continued for at least 10 days after the infecting feed to prevent infection from developing, and that the daily dose given has but little influence apart from the fact that with very large doses (30 gr.) the period for which the drug has to be given to prevent development of infection is a little shortened. It is concluded from these observations that quinine has little, if any, action on sporozoites, and that the mechanism by which development of infection is prevented is similar to that by which a cure is effected.

Value of the Malaria Treatment of General Paralysis.

Up to the time of writing a sufficient period has elapsed to enable a judgment to be formed regarding the effect of the malaria treatment in respect of 84 patients suffering from general paralysis. In presenting these results we have relied on the judgment of the medical officers in charge of the patients at the various mental hospitals. Of the 84 patients treated 14 have died, most of them immediately, or shortly, after the completion of the course of malaria treatment; although all these cases had been treated with quinine before death and parasites had disappeared from the blood, nevertheless it is impossible to affirm that in none of them was death accelerated by the malaria. No noticeable change in mental or physical condition has been observed in 20; with regard to these cases, however, it is to be borne in mind that in the ordinary course of events many of them would now be dead. In ten there is definite physical improvement, but no change in the mental condition. In 17 there is great physical and distinct mental improvement. Finally, in 23 the mental and physical improvement has been so great that the patients have been, or are about to be, discharged from the mental hospitals. In a number of the cases the improvement has been maintained for many months—in some for as long as a year—and quite a number are back at their old occupations. As time goes on, it may be found possible to discharge still others of these 84 cases for, as Wagner-Jauregg writes, "The maximum of the improvement does not manifest itself at once at the end of the period of fever but does later. On the contrary, the improvement continues often for a long period, so that in many cases the result seemed to be an incomplete one where later however a complete remission came to pass." Whether the improvement is temporary or permanent only time can decide, but the results already achieved can only be regarded as remarkable when it is realised that no patient suffering from general paralysis had previously been discharged from the mental hospitals in question.

THE WILLIAM DUNN LABORATORIES.

On Friday in last week Lord Balfour, Chancellor of the University, opened at Cambridge the new William Dunn Laboratories for the study of biochemistry.

The magnificent donation to the University of £210,000 from the estate of the late Sir William Dunn reached the University by a series of fortunate accidents, for the residue of this city merchant's great fortune was left in the hands of trustees to be used for the "alleviation of human suffering," no more precise directions being given. The executors of the will were the directors of the Commercial Union Assurance Company, who appointed a small committee to assist them in the responsible task of allocation, and the accidents referred to were the various circumstances which led to the decision of this committee before whom so many and various opportunities of benefiting mankind were unrolled. The final recommendation of this body was that a well-equipped and thoroughly modern building for the study of biochemistry should be erected at Cambridge, and Lord Balfour, in accepting the great gift in the name of the University, indicated in a convincing way how the developments of biochemistry are being now employed, with a promise of still greater employment in the future for the arrest and prevention of disease.

The Buildings.

The new laboratories are situated on the east side of Tennis Court-road, on part of the old park of Downing College and in immediate proximity to the science schools. They form a handsome block of three stories, having at the top a large general laboratory, and below a quantity of smaller rooms elaborately equipped for carrying out any procedure cognate to research in biochemistry. There is also a large library, which has been made the subject of a most generous donation of £2000 from Sir Jeremiah Colman, the chairman of the Dunn Trustees.

The opening of the laboratories formed but a brief ceremony. Sir Jeremiah Colman, with whom were his co-trustees, the Hon. A. H. Holland-Hibbert, Sir James Leigh-Wood, and Mr. C. Seligman, formally handed over the buildings to the Chancellor, congratulating his old University on having obtained the prize in a field where there had been keen competition, a result which he attributed to the high position which the medical school of the University had made for itself.

The Progress of Biochemistry.

Lord Balfour, in receiving the gift of the laboratories, said that the problems of disease could be approached and were being steadily solved in certain directions along lines of pure chemistry and pure physiology. But he showed that research along the double track of biochemistry held out a more than double promise, chemical research with a biological basis offering infinite possibilities for fruitful discovery. He congratulated the trustees of Sir William Dunn's estate upon the business acumen which had brought about appreciation of this fact, and upon the wisdom which had prompted them to endow research in order that efforts for the alleviation of human misery might be directed by theories having behind them broad and intensive experimental study. On the breadth of sound research he laid especial stress. Taking malignant disease as a typical example of a widespread source of human misery whose origin was as yet unexplained, he hazarded the conclusion that when the causes of cancer became known, so that effective measures of control or prevention could be taken, this splendid consummation would be the result of a discovery made with no special consideration of the phenomena of morbid growths, but one which opened up some generalisation which in its turn would shed a flood of light upon the accumulated knowledge of generations of medical observers. He concluded by expressing his confidence in the leadership of Prof. Gowland Hopkins, the devotion of his collaborators, and the promise held out by the great work of biochemistry now proceeding in the Cambridge school.

A Dinner to the Trustees.

In the evening a dinner was given in honour of the trustees at Trinity College, the Master, Sir J. J. Thomson, presiding. The Chancellor, the Vice-Chancellor, many heads of houses and professors, as well as a representative group of guests were present to meet the trustees.

PARIS.

(From our own Correspondent.)

Hospital Ventilation.

To maintain the air of a hospital ward as closely approximate as possible to the exterior air, provision must be made for continuous ventilation so that the air of the ward is renewed three times in the hour, and although it is easy to preserve an equable temperature during the winter, it is a more difficult matter in summer. Dr. Jules Renault recently demonstrated to the Academy of Medicine the apparatus which he used to maintain the constant ventilation of his wards in the Hospital San Louis (Grancher Annexe) by warm air in winter and cool air in summer, with an adequate percentage of moisture at all seasons. The installation is designed as follows: in the basement there is fixed an intake pipe and two pieces of apparatus which regulate the temperature and humidity: in the ward there are distributing pipes for the fresh air, exit pipes for the foul air, a regulating switch-board, and a registering thermometer and hygrometer. The intake opening is situated about two metres above the ground in the courtyard and is furnished with a retaining-box for dust, containing a filter of about 40 cm. in thickness and composed of a series of sieves of woollen mesh placed at suitable distances one on top of the other. This removable filter retains all its properties for several months without causing any appreciable resistance to the passage of the air. It needs only to be cleaned twice a year. Further, an electric fan allows the intake of air to be conveniently regulated. The fresh air is driven through a large casing which divides into two smaller casings passing through the basement, and terminating in the regulator apparatus. This is composed of (1) a radiator to heat the air, formed of copper tubing through which steam at a very low pressure passes. (2) A radiator for the cooling of the air, larger in size and placed at the lower part of the apparatus and also formed of copper tubing, through which passes a current of cold water from the town main at a temperature of about 13° C. A two-way valve worked from the switch-board in the ward permits the air to be directed either through the heating apparatus or through the cooling apparatus. (3) A moistening trough in which the air passes above water which is made to evaporate by steam at low pressure in a coiled tube. The amount of water evaporated varies with the area of the coil brought into contact with the water, and a switch on the switch-board allows this area to be altered at will. The treated air is then conducted by water-tight and properly insulated casings to four distributing outlets fixed along the walls of the wards. These outlets are constructed in such a fashion that the air exits from holes in the sides along the walls and does not blow directly down on the patients. The beds are placed in the middle of the ward in cubicles arranged around a central pillar. The air is withdrawn from the room from the upper part of the windows by means of three vents furnished with balanced aluminium valves which rise on positive pressure in the interior air. The movement of these valves shows clearly that the air passes out freely and that the ward is adequately ventilated. At any hour of the day or night the composition of the internal air is similar to that of the exterior air. The temperature is maintained in winter between 20° and 21° C., and in summer between 21° and 23° C., even when a thermometer placed outside indicates 30° C. The hygrometer reading varies during the year between 40 and 50 per cent. From the physiological point of view the air is maintained sweet and fresh. Finally, from the pathological point of view colds, bronchitis, bronchopneumonias become rare sequelæ in the wards in winter, and heat-stroke in summer is obviated.

The Medical Coupons Scandal.

The tribunal on those involved in the medical coupons scandal, details of which were set forth in my letter published in THE LANCET of June 16th, 1923, has now pronounced judgment. It will be remembered that on Sept. 23rd, 1923, following a long inquiry, several doctors were found guilty of swindling, their accomplices being chemists, presidents of associations of old soldiers, and agents. They had created a vast organisation in order to turn to their own profit the law which authorises payment by the State for medical care and drugs given to those wounded in the war. The swindle had gone on for three years on a grand scale, and it is estimated that the cost to the taxpayers approached 20 million francs. Eight doctors and four chemists and ten other persons were found guilty, several of the sentences being very severe. For example, one doctor was given two years' imprisonment, 3000 francs fine, and ten years' of interdiction from the practice of medicine. He was also ordered to pay 33,123 francs to the State, 2500 francs damages to the Union Fédérale des Mutilés et Blessés de Guerre, jointly with three other culprits, and one franc (corresponding to one farthing damages), to the Syndicat des Médecins de Marseilles. This appears to be the most severe sentence given to any of the medical men, whereas pharmacists and non-professional persons were given sentences more or less heavy. The president of the Union Fraternelle des Éprouvés de la Guerre is to be imprisoned for three years. No one in any country will fail to rejoice that such flagrant abuse of professional privileges met its deserts.

Evolution of Hepatic Cirrhosis according to Sex.

In making an analysis of the observations of cirrhosis of the liver recorded at the clinic of the Hospital of St. Antonine during the years 1922–23, Prof. A. Chauffard and Dr. Brodin found that in man the evolution of the condition differed from that in woman. In the man there was found the classic picture, with liver atrophy and recurring ascites, necessitating repeated tapping which resulted eventually in death from cachexia. In the woman, on the other hand, the liver was generally hypertrophied and the disease developed by spurts, showing occasional improvements varied by short relapses. Finally, after a longer or shorter quiescent period new features might arise, frequently acute tuberculosis. The cause of death in women was not a slow cachexia but hepatic insufficiency. This difference in development seems to be due to lower powers of resistance in the female liver against infections and intoxications, particularly that of alcohol.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Isolation of the Virus of Foot-and-Mouth Disease.

BEFORE the Microbiological Society of Berlin, as I have already informed you, Prof. Frosch, head of the bacteriological department of the Veterinary College, reported that he had succeeded in discovering the virus of foot-and-mouth disease, which hitherto could not be rendered visible by the ordinary optical methods. Together with Prof. Dahmer and Prof. Köhler, of the Zeiss works in Jena, he used ultra-violet rays to demonstrate the germ, which was then cultivated on a solid nutrient medium. It proved to be a bacterium of very small size. The author gave a report of the technique of his method and of the successful inoculations made with the virus. The discovery, which is of great scientific and practical value, is now being examined in the Robert-Koch Institute in Berlin.

Abortion in Germany.

The incidence of abortion has become very frequent in Germany. In the *Aertzliches Vereinsblatt* a country medical man states that the practice of inducing abortion, which hitherto was a prerogative of the cities alone, has now become widely spread among the rural population. He states that nearly as often as he ascertains pregnancy in a woman he is called a few days later to her because she is aborting; the midwives complain that the number of births has recently very much decreased. There exists indeed a society which delivers lectures throughout the country under the pretext of giving contraceptive information, and it is an open secret that they give such permissible advice, while they also teach pregnant women how to bring about miscarriages. The author wishes to draw the attention of the authorities to that society which, notwithstanding its harmless name, has illegal aims. The views of the correspondent are strongly opposed by a Berlin medical man who is known to be an active member of the Communist party and who declares that the abortion epidemic is caused by economical reasons only, mothers being afraid of becoming unable to procure food for the child. According to this Communist doctor, it is quite unreasonable to prosecute for induced abortion. In Russia the penalties for illegal abortion were abolished immediately after the revolution, and it became legal to interrupt pregnancy for economical reasons provided it was sanctioned by a State medical officer and performed in a State hospital within the first three months of pregnancy. Moreover, the Russian law provides that a pregnant woman shall be paid her full wages even if owing to her state she is able to do less work; she also receives her wages for two months after her delivery even if totally incapacitated for that time, and an extra benefit to enable her to buy things necessary for her child. Commenting on the present situation, the editor of the *Aertzliches Vereinsblatt* says that it seems unreasonable that the Russian law should permit induction of abortion for economical reasons when it supports women during their pregnancy and after the birth in such a lavish way as described by the correspondent. Germany ought to follow the example given by Russia in the care of pregnant women, but to decline to make criminal abortion lawful, even if performed by a State medical officer.

Insurance Practice in Britain and Germany Compared.

The many difficulties in insurance practice induced the Berlin Medical Chamber to inquire into the state of things in other countries. The Chamber therefore approached the British Medical Association for information and their request met with a friendly reception, as Dr. Cox, the secretary of the Association, sent to the Medical Chamber articles he had written on insurance practice in England in the *Journal of the American Medical Association.* These are printed in full in two issues of the official organ of the Berlin Medical Chamber under the title of "Seven Years of National Insurance in England." By special permission of the author and of the editors of the *Journal of the American Medical Association* it will also be published as a separate volume. The articles are of great interest, as they show that the principal feature of the English law from a medical point of view is that no medical man desiring to practise under the Insurance law is excluded from so doing, except for serious reasons. Also, the English law benefits a smaller part of the population than the German one, and that insurance work forms only a small part of the income of the average English doctor, whilst in Germany insurance practice is the principal and sometimes even the only source of income of most practitioners. The number of medical men doing work under the Insurance law, as quoted by Dr. Cox, is 12,850 of 24,000 medical practitioners residing in England, Scotland, and Wales, being about 55 per cent. This is a much smaller percentage than that of Germany, where only a few medical men are entirely independent of club practice. It is true that in the larger towns many medical men, particularly specialists, have consulting rooms for club patients outside their residence, or in their residence special hours for them, where they come not in touch with private patients. It certainly seems to be an advantage that club patients are in this way able to consult leading specialists under the club tariff; otherwise the middle classes under present financial conditions would be unable to get specialist advice. A great advantage of the English law is the determination and the payment of the fees by the Government, so that battles with the clubs and strikes are more easily avoided than in this country. The issue of the recent big medical strike in Germany is a warning example of the disadvantages caused by such incidents both to the medical profession and to the insured. It may be noticed that since my last letter the medical strike which had then ceased in the greater part of Germany has been called off in Berlin also. Both parties have come to an armistice until July 1st, the conditions being that the medical men will continue to attend club patients as private patients at moderate fees, but that those fees are no longer paid, as during the strike, by the patient himself but by the club to which the bills must be sent by the medical attendant. During the armistice both parties will enter into negotiations for a definite settlement of the system of medical attendance.

German Medical Men in Afghanistan.

The economic conditions of Germany have induced many medical men to emigrate into foreign countries where there seems to be some hope for them to earn a livelihood. As already mentioned in these columns, the Afghan Government some time ago had asked German medical men to settle in that country. Notwithstanding the warnings of medical men with experience of hot climates, a large party made the journey at their own risk from Germany through Russia to Afghanistan in the hottest time of the year, the result being that several members of the party died on the journey from malaria or dysentery, and a number of the survivors became seriously ill. In this connexion the *Leipziger Verband* warns medical men against undertaking private arrangements with foreign Governments without the assistance of the *Verband,* pointing out that the rush for such appointments is undignified and tends to lower the standing of the German medical profession. This is the more the case as the Afghan disaster is not the only one caused by the inexperience of German medical men, but that similar facts are reported from elsewhere.

Retirement of Prof. Gottstein.

Prof. Gottstein, the chief of the Prussian Medical Department, has retired from office, the law providing that all Government officers must do so on reaching the age of 65 years. Prof. Gottstein, who after the revolution had succeeded Prof. Kirchner, had a difficult task, as he took office at a time when Germany had just passed through the dangers of war and of revolution with the concomitant bad hygienic conditions. He did good work in arranging for the instruction of Government medical officers by instituting an academy for social hygiene, where he will continue to lecture after his retirement. His work in the care of tuberculous, venereal, and cancer patients respectively was made difficult by reason of the small sums the Treasury could spend for hygienic purposes. He will be succeeded by Dr. Dietrich, a senior member of the department.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Temp. Surg. Lieut. A. E. Phillips is transferred to the Permanent List.

J. A. Cusack and V. F. Walsh to be Surg. Lts.

The following appointments have been notified: Surg. Lt.-Comdr. (D.) W. E. C. Sampson, to the *Victory,* for R.N. Barracks, Portsmouth; Surg. Lt. (D.) H. J. Luck, to the *Warspite.*

ROYAL ARMY MEDICAL CORPS.

Capt. S. J. Barry to be Maj.

Capt. C. Russell retires receiving a gratuity and is granted the rank of Maj.

TERRITORIAL ARMY.

Maj. R. Phillips to be Lt.-Col. and to command the 47th (2nd Lond.) Casualty Clearing Station.

Capt. J. Kinnear to be Maj. (prov.).

Capts. A. L. Taylor (late R.A.M.C.), K. Simpson (late R.A.M.C.), and C. Shaw-Crisp (late R.A.M.C., Militia) to be Capts.

Capt. A. Rodd, R.A.M.C., to be Divl. Adjt. 43rd (Wessex) Divn., vice Capt. W. W. S. Sharpe, R.A.M.C., vacated.

Lts. C. H. A. Alderton and R. H. Hadfield to be Capts.

Sanitary Companies.—Lt. A. Massey (late R.F.A., T.A.) to be Capt. (prov.) with pay and allowances of Lt.

Supernumerary for Service with O.T.C.—Maj. C. E. Searle to be Lt.-Col.

ROYAL AIR FORCE.

G. P. O'Connell is granted a short service commission as a Flying Officer.

Flight Lt. (Hon. Squadron Leader) H. B. B. Greene relinquishes his temporary commission on ceasing to be employed and is permitted to retain the rank of Flight Lt.

INDIAN MEDICAL SERVICE.

The King has approved the grant of a temporary commission as Lt. to Capt. Shiva Shankar Gupta, late I.M.S., who relinquishes the rank of Capt.

BRITISH EMPIRE EXHIBITION, WEMBLEY:

HEALTH IN THE TROPICS.

> "This Exhibition . . . stands for the coördination of our scientific knowledge and a common effort to overcome disease . . . in many parts of the Empire."—H.M. THE KING.

II.

THERE are many aspects of medical service in the East which require consideration apart from general therapeutics. Among others is the provision of proper obstetrical aid, and in this connexion the photographs in the exhibition of Indian home nursing, as it is, and as it should be, give food for thought, the wonder being that the puerperal morbidity-rate is not a great deal higher. Religious pilgrimages are a source of great danger from the point of view of disease dissemination, and the illustrations of the elaborate arrangements made at various places, especially at Suakim, are worth seeing. Looking at the exhibits from Burmah and Arakan one does not envy the registrar his task if he has to prepare his reports from the chipped and coloured pieces of bamboo and wood that form the medium of registration of births and deaths in these parts.

In the light of what we hope will be a reawakened interest in the medical affairs of our many dominions it may not be out of place to present in a short form some of the reports in our hands from medical officers in a few representative parts of the Empire.

The majority of these deal with the year 1922, a few of them with the year 1923 in part or whole; they may be roughly grouped into three sections: (1) New Zealand and New South Wales; (2) certain African territories, mainly to the east of the continent; (3) the great tea and rubber districts of the Malay Archipelago, with which may be placed a report on the North-West Frontier of India.

(1)

The report from *New Zealand* is an excellent one, the only adverse features being a declining birth-rate and an outbreak of typhoid fever, the latter due to water pollution in the lava catchment area of Mount Albert. The outbreak was rapidly taken in hand and with a new main water-supply to the area the disease was eradicated. Dr. Truby King is the moving spirit in the infant welfare work, and the State-subsidised home nursing staff is increasing in numbers. The figures of the school inspection staff are interesting; in all 34,400 children were examined and the following defects found:—

		Per cent.
Dental defects		67·16
Defects other than dental—		
Postural and structural trunk and chest ..	26·03	60·40
Cervical glands	11·25	
Enlarged tonsils	11·23	
Subnormal nutrition	7·41	
Goitre	6·20	
Defective vision	3·18	
Defective hearing	0·79	

The infantile mortality-rate is 41·9, the lowest to be found in any of the reports and the best ever realised in New Zealand. There are many Maori health councils doing good work and receiving widespread support from the Maoris themselves.

The report from *New South Wales* does not compare favourably. There was an outbreak of diphtheria with 6854 cases and 306 deaths, and also a reintroduction of plague after a lapse of 12 years, but only two human beings were infected, although large numbers of infected rats were killed. The State has no control over midwives, many unqualified women practise, and puerperal fever is not notifiable by private hospitals; a Bill to remedy this state of things has been before Parliament for about three and a half years, but has not yet become law. The Rockefeller Institute is coöperating with the State authorities in the Tweed River area against hookworm, treatment is offered gratis and lectures and advice are given; the defective sanitation is being dealt with vigorously. The Pure Food Act of 1908 is bearing most excellent fruit, only 3·2 per cent. of the milk samples were found adulterated during the year. Phthisis, diphtheria, and typhoid were the chief killing diseases in 1921, the death-rate from phthisis in New South Wales, however, is only half that of England. The infantile mortality in Newcastle (N.S.W.) is 247 per 1000, and in this area there is a grave house shortage, which, however, is being tackled as rapidly as possible.

(2)

Among the reports from Africa that from *Kenya* makes interesting reading. The European health is best in the southern highlands, where for a tropical region a fairly temperate climate prevails. In 1922 there were no epidemics and the general health was good; many hygienic and sanitary works are held up on account of financial stringency, but good headway is being made nevertheless. The native death-rate is approximately 19–23 per 1000, the European only 9·04.

Tanganyika presents a comprehensive report, of which we publish a substantial abstract on p. 1039. The territory is a large one, some 365,000 square miles in area, with a native population of about four millions. Particular attention is drawn to the sterility of the Swahili women, partly due to venereal disease and partly to in-breeding. The survival rate of the children is adversely affected by congenital syphilis and by the infanticidal practices of the native medicine-men, which are now to a certain extent being put down by the new ordinances. The one ominous factor in the report is the mention of an introduction of trypanosomiasis into this area, where the tsetse-fly abounds and has hitherto been free from infection, active measures are therefore being taken to prevent the fly becoming infected. The report is interesting as showing in a fairly representative district the difficulties of medical administration among the natives of Africa.

Swaziland has had a good year as regards health, with very little malaria and practically no enteric. Syphilis is very prevalent among the natives, and during the year there were outbreaks of both mild small-pox and mild influenza, the death-rates of both being very low, in the case of the former due no doubt to the extensive vaccination of the native population.

Somaliland is evidently very healthy for Europeans; among the natives the only widespread infection appears to be venereal disease.

(3)

This group covers a wide field, chiefly in Malay and India. Visitors to the Malay pavilion at Wembley will see a model and a very good collection of photographs of the quarantine station at St. John's Island, *Singapore*, the largest of its kind in the Empire, and they will see what efforts are made to localise epidemics likely to be spread by sea-borne traffic. The death-rate in Singapore in 1922 was slightly greater than the birth-rate, largely owing to the high infantile mortality-rate, much of it the result of tetanus. The European death-rate is low, being 9 per 1000.

In *Brunei* malaria and ankylostomiasis are very prevalent, as is also venereal infection, which owing to difficulties with the natives is not easy to treat in the early stages. Since small-pox decimated the area in 1905–06 there have been no serious epidemics of any kind.

The report from the *Federated Malay States* shows an increase in the female Chinese population, which is supposed to herald a more permanent settling by the Chinese, and is welcomed by the authorities. The native birth- and death-rates almost balanced for 1922, and the infantile mortality-rate was 170·8. Yaws and syphilis are being energetically treated with novarsenobenzol; as regards the former, the disease is almost eradicated. The passing of the Midwives Registration Act and the fact that the vaccination-rate exceeds the birth-rate are both satisfactory points. As regards mental diseases the statistics are worthy of notice; although the incidence of malaria is enormous, only 78 cases of mental disease were attributed to it, 35 and 37 cases among the Chinese were attributed to syphilis and alcohol respectively and only two to opium.

In some of the *Unfederated Malay States* the natives are highly infected with ankylostomiasis and ascaris lumbricoides, but there have been no serious epidemics of other diseases. The Malay women are not tolerant of the trained midwife, and this together with bad sanitation gives a high infant mortality-rate, highest among the Indians (220), lowest among Europeans (37). Puerperal fever takes a heavy toll of the women. Health departments and school medical services are rapidly increasing. The cancer-rate among the natives is very low, as stated (0·25 per 1000), but as post-mortem examinations are not frequently held this figure is open to question, but even when allowances are made it is striking. Householders are very apathetic in helping with anti-mosquito work, which is much hindered thereby.

In *Ceylon*, an island splendidly equipped with all manner of medical requisites, the general health is very good, and here again the cancer-rate is noticeable as being bottom of the list of killing diseases with only 101 deaths per million of the population; "pyrexia" and infantile convulsions head the list with 4422 and 3028 deaths respectively.

In *Assam*, Schick testing for susceptible contacts in the diphtheria epidemic was most successful, this being the first set of tests carried out in India. Cholera in the absence of preventive measures took 16,000 lives, and "economy" is leaving malaria and kala-azar with a much higher toll than need be, as the public health staffs are being cut down.

The Director of Public Health for the *North-West Frontier* district of India has presented a report (see p. 1038) valuable for many comparisons that it shows, and the figures given of cantonment life ought to be sufficient to impress the authorities with the great and pressing need for extending rather than curtailing the sanitary services. Lieut.-Colonel F. P. Mackie's experiments with cholera vibrios in unripe and over-ripe fruit are mentioned, and the consequent necessity of eating only good fruit is obvious in the presence of an epidemic of cholera. The relative merits of cinchona and quinine are briefly mentioned. Unfortunately, it would seem that retrenchment in health matters is the rule everywhere; one wonders what the national balance-sheet would show if only the losses from this policy could be shown in pounds, shillings, and pence for comparison with the cash saving effected by the curtailment. The jail accommodation is somewhat below the requirements, but notwithstanding this the health of the prisoners was good. Interesting photographs are shown in the Tropical Health Section at Wembley of various jails in India; these give a good impression of the general arrangements and the physique of the men.

IMPERIAL SOCIAL HYGIENE CONGRESS AT WEMBLEY.

May 12th–16th.

First Day's Proceedings.

Mr. J. Wheatley, the Minister of Health, supported by representatives of the Governments of the Overseas Dominions and India, gave an excellent send-off last Monday at Wembley to this Congress, organised by the National Council for Combating Venereal Diseases. Mr. Wheatley said that he attached great importance to the conference and was pleased at its representative character. He extended a cordial welcome to the delegates from overseas. He specially referred to the results achieved by the mission organised by the National Council, in coöperation with the Colonial Office, which visited the West Indies, the Far East, and the Mediterranean to develop a scheme for the protection of our merchant seamen. In the course of his remarks, he mentioned that in the production and distribution of health we are all Socialists, and, further, that we are all opposed to free trade in disease. Mr. Wheatley concluded by saying he would await the results of the deliberations of the Congress with much interest, as they would be of the greatest assistance to him in settling what modifications of policy were now desirable.

Sir George Newman, Chief Medical Officer of the Ministry, gave an address on the Present Position of Government Action in Venereal Disease, which included an admirable résumé of the attitude to and treatment of venereal disease in the nineteenth century, the great advances in our knowledge of syphilis made in the early years of the twentieth century, and the events which led to the launching of the State-aided scheme for England and Wales in July, 1916. Sir George Newman gave the reasons why the Ministry up to the present time has been opposed to any scheme for notification of these diseases or for compulsory treatment, and he showed why it is impossible for the Government to give its official support to "self-disinfection" or the sale of disinfectants as a policy. The Ministry are of opinion that very much more can be done in the matter of the education of the public than is done at present, and that further facilities and improvements can be made in order to attract patients to the clinics and secure continuity of treatment.

Sir Leslie Mackenzie, member of the Scottish Board of Health, gave particulars of the working of the scheme in Scotland, in which country, as in England, there was evidence of a decline in the prevalence of these diseases since 1920. The Scottish Board had at present under consideration an application for approval to a scheme for notification and securing continuous treatment, and they had not yet given their official reply. He was in favour of more propagandism, and educational facilities had not been used to the full. But he asked, "Is there no case for an experiment in notification?"

At the afternoon session, Dame Rachel Crowdy, Director of the Social Hygiene Section of the League of Nations, read a paper on the Traffic in Women and Children, and explained that the League is only indirectly concerned with prostitution. The advisory committee of the League on this matter has, however, recently issued a questionnaire on the "licensed house" system to all members of the League. Particulars of the replies received up to date were included in Dame Crowdy's paper, and appear to indicate a considerable body of opinion that licensed brothels provide a ready market for the white slave traffic. There was also evidence that prostitutes in licensed brothels contract venereal disease more frequently than those living independently.

Prof. Winifred Cullis (London School of Medicine for Women) put in a strong plea for the teaching of biology, in preference to chemistry and physics, in the elementary schools. It was easy to make it interesting and connect it up with sociology. If taught to elementary scholars, it could readily be continued with adolescents. It ought to be in the curriculum of the training colleges. Unfortunately a regulation of the General Medical Council put obstacles in the way of biological teaching in schools, and she hoped the medical profession would get this regulation abolished.

Dr. F. J. H. Coutts, Ministry of Health, strongly supported Prof. Cullis's plea for the teaching of biology.

Sir Arthur Newsholme, in a paper entitled Some Aspects of Social Hygiene, developed the idea of the right teaching of sex-hygiene, beginning with instruction in self-control from infancy onwards.

Miss Alison Neilans, Secretary of the Association for Moral and Social Hygiene, in an effective speech, said we can do little by law or police, but must change public opinion. They in that hall did not really represent public opinion. According to public opinion prostitution was inevitable. We must alter public opinion by attacking the double standard and getting a re-statement of the basis of sex morals and ethics.

Mrs. Falconer, of the American Social Hygiene Association, also spoke on educational methods.

The first day's proceedings were chiefly set apart for invited speakers. Opportunity for general discussion came later.

Public Health Services.

THE HEALTH OF THE CITY OF LONDON.

THE estimated population of the City for the year 1923 was 13,180. Dr. W. J. Howarth gives in his annual report some interesting particulars from the census returns. For the first half of the nineteenth century the population of the City was stationary at about 125,000, but since 1850, owing to the efforts of the sanitary authority and the demands of business, it has declined census by census to the present figure.

Housing and Personal Health.

The erection of commercial buildings of greater height has "obstructed" many of the remaining dwellings and rendered them "unfit." Thus there are two unhealthy areas waiting to be dealt with as soon as alternative accommodation can be found for the persons to be dehoused, and for these occupants Dr. Howarth suggests tenements should be erected on a site to be obtained as near the City boundaries as possible. Using the standard of two persons to a room as a basis, the census shows that 109 families are living under conditions below such standard. Of the small City population, 1292 males and 571 females work outside its area. On the other hand, the number of persons who live outside the City but come into the City to work daily is 288,626 males and 115,678 females.

The statistics of the small residential population when analysed are founded on figures too small to justify deductions from the comparison between one single year and another; but for 1923 the principal were: Birth-rate 8·2; death-rate 11·5; infant mortality-rate 81; tuberculosis death-rate 1·3; cancer death-rate 1·1; death-rate from respiratory diseases and influenza 1·8; and maternal mortality from childbirth 9·0. A table included in the report shows that cremation does not make rapid progress. Thus the highest total of cremations in the United Kingdom in any one year was 2031 in 1919 and in 1923 the number was 1986. Dr. Howarth quotes Dr. J. S. Owens as being responsible for the statement that London now receives nearly 30 per cent. more sunshine that it did in 1881, and expresses the opinion that if the companies concerned gave special terms for the gas and electricity used for heating and cooking purposes, the further improvement in the atmosphere would be so marked as to create an agitation against the unnecessary use of common coal. It is disappointing to learn that the very successful treatment of parturient women, suffering from syphilis, carried out through the Metropolitan Asylums Board, at Thavies Inn Infirmary, is not used as it might be. The Board think the facilities provided are not sufficiently well known to medical practitioners and a circular letter on the subject has been sent to every practitioner in the City.

Purity of Milk and Bread.

In view of the fact that milk-vendors, prosecuted for selling milk below the standard, frequently allege that the milk has not been tampered with, Dr. Howarth has arranged for some experimental sampling to be undertaken in order to illustrate how easily careless methods on the part of the retailer may lead to an apparent abstraction of fat or even an addition of water. Some of the examples given are the poorness in fat of the last milk in a counter pan emptied by a dip measure, or of the milk from the tap of a churn on a "pram" unless it is regularly stirred with a plunger during its round. Careless distribution of milk from railway churns after a long journey is another example cited, and another less common is the careless thawing of milk which has been in cold storage. A sample of new milk from Holland was reported to contain only 2·38 per cent. of fat. Some vendors of bread are in the habit of exchanging new bread for old, and this is mentioned as a possible means of spreading infection, and the desirability of bread being enclosed in wrappers is also referred to. As wrapping keeps the bread new for a longer period, the general adoption of the latter practice would lead to the disappearance of the former.

Meat Inspection.

Under the heading of meat inspection, Dr. Howarth comments on the large proportion of home-killed pig carcasses affected by tuberculosis. He suggests that there is much carelessness among pig feeders, especially in the use of milk from tuberculous cows. On the other hand, little tuberculosis is found among the carcasses from Holland, which country continues to be the chief source of the pork-supply. The quality of Australian beef has improved and the new method of cutting the hind quarters has given satisfaction to the trade, but there is no improvement in the dressing and finish of New Zealand beef. At the Aldgate slaughterhouses six calves of ages varying from 2 to 9 months were found to be affected with generalised tuberculosis, and in none of these were lesions found in the intestines or mesenteric glands. Fifty per cent. of the cows affected by generalised tuberculosis and 16 per cent. of all the tuberculous cows had lesions in the mammary glands, and three had, in addition, lesions in the uterus. All these cows had been presumably producing milk up to the time of slaughter. These figures, Dr. Howarth points out, confirm the need for the re-introduction of the Tuberculosis Order of 1914. Some authorities wish to have the inflation of carcasses prohibited. As long as a clean mechanical apparatus is used for the purpose, Dr. Howarth considers no strong argument can be advanced against the practice, except that it may give a fictitious value from the improved appearance.

A Diminution of Rats.

The scheme of rat repression shows progress. Thus Mr. Mayne, who is in charge of this work, reports that the proportion of buildings inspected which were found to be infested was considerably lower in 1923 than in 1922. One of the weak points in the scheme is that the responsibility falls on the occupier, and that in many cases considerable structural alterations are necessary in order to obtain a satisfactory result. Buildings may be infested with either the black or the brown rat, and the first step of the rat officer is to find out which species is the cause of trouble. If the black rat is the intruder, the examination of the building begins at the roof; if the brown rat, the inspection begins in the basement, and it is frequently necessary to test the drainage system. The manager of one of the larger railway companies is of opinion that rats are less numerous than formerly, and rat-catchers engaged in the City took fewer rats in 1923, in spite of having contracts with a larger number of City firms.

INFECTIOUS DISEASES IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 3RD, 1924.

Notifications.—The following cases of infectious disease were notified during the week—namely: Small-pox, 132; scarlet fever, 1246; diphtheria, 642; enteric fever, 67; pneumonia, 1357; puerperal fever, 44; cerebro-spinal fever, 11; acute poliomyelitis, 4; acute polioencephalitis, 4; encephalitis lethargica, 278; dysentery, 7; ophthalmia neonatorum, 118. No cases of cholera, plague, or typhus fever were notified. Cases of encephalitis lethargica, more numerous than in any previous week, were notified in the following counties: London, 50; Chester, 6; Derby, 9; Durham, 7; Essex, 5; Gloucester, 14; Kent, 5; Lancaster, 35; Northumberland, 18; Stafford, 9; Surrey, 5; Warwick, 29; Worcester, 4; Yorks, East Riding, 7; West Riding, 42; and elsewhere in smaller number.

Deaths.—In the aggregate of great towns the deaths from influenza fell from 218 to 167. In London the deaths from diphtheria numbered 13 and those from measles fell to 40; deaths from influenza rose from 21 to 27.

Correspondence.

"Audi alteram partem."

THE MEDICAL TREATMENT OF CATARACT.

To the Editor of THE LANCET.

SIR,—I read with interest the article by Mr. Inglis Taylor in THE LANCET of April 5th on the medical treatment of cataract, for I certainly think—and have acted on this for some years now—that we ought to do something more for our cases of commencing cataract than simply tell them to come back to us when they are ripe for operation. In my Doyne Memorial Lecture, read at the Oxford Ophthalmological Congress in August, 1922, I made an attempt to collate and estimate our knowledge of the ætiology of cataract, and I am prepared to welcome any attempt to treat cataract medically. We shall not, however, arrive at any sound line of treatment except from a correct ætiology.

Prophylaxis is most important. I cannot agree with Dor's theory of hydration. Chemically this theory is wrong. For instance, to speak of hydration which implies nothing more than added water in the same breath with ferments which are hydrolytic agents giving rise to chemical decomposition is inaccurate, and ought not to go unchallenged. Hydrolysis, as I have shown, is undoubtedly the first chemical change taking place in the lens in a genuine cataractous process. I omit from this statement coagulation of protein such as occurs when the crystalline is put into a solution of sugar, or in some contusion opacities of the lens which I have seen clear completely in ten days even when vision is as low as 6/60. Calcium taken internally or applied locally may act by reducing the relative acidosis which is so common in subcapsular senile cataract, but in my experience potash is to be preferred, and I think that any resulting good is due to this element, which is a cell food and a normal constituent of the lens. Potash is wanting or deficient in cataract.

I have seen in many cases great improvement in the vision follow from medical treatment. To attempt to treat all alike with any particular remedy without investigating to the best of one's ability the ætiology savours of empiricism. For instance, I have recently seen a case of double spotted cataract, the onset of which coincided remarkably with the development of an ovarian cyst which was eventually removed. The opacities now are, I consider, stationary and may remain so for some years as the patient is considerably below the average age of onset of so-called senile cataract. I see no reason why we should not feed the lens on potash in such a case, but so long as the cause remains operative there would be little chance of a cure. Again, I have shown that there is such a cataract as a "refractive cataract" due to uncorrected error of refraction in early life; the treatment of this is, of course, prophylactic.

The time has come now to study each case of cataract carefully with reference to its ætiology; we must not be content to lump all types together under one heading.—I am, Sir, yours faithfully,

Bath, May 5th, 1924. J. BURDON-COOPER.

A CRITICAL EXAMINATION OF PSYCHO-ANALYSIS.

To the Editor of THE LANCET.

SIR,—Dr. R. M. Riggall in his letter appearing in to-day's issue of THE LANCET charges me with being "incapable of understanding the psycho-analytic conception of the unconscious." This may be correct in a way—namely, in the way in which I am incapable of understanding the conception of ghosts and spirits. It appears to me that the psycho-analyst conception of the unconscious is the result of anthropomorphic tendencies with respect to the inner world, as the creation of ghosts, demons, and deities is the result of the same tendencies with respect to the outer world. Owing to this incapability of mine Dr. Riggall finds it "difficult to know what kind of proof I require." I am sorry, but I cannot help him. I could not say off-hand what proof I should require to convince me of the existence of ghosts and spirits, but I am willing to examine dispassionately and without bias *any* "proof." However, as I said before, the "unconscious," qua unconscious, is not the key-stone of the psycho-analytic arch, for Pierre Janet, Morton Prince, and others assume an unconscious though totally different from the psycho-analytic one. But the assumption of even that sort of "unconscious" is, I hold, quite unnecessary. The key-stone to the psycho-analytic arch is the method of dream-analysis, &c., for penetrating into it. Freud advanced five reasons to show that the results of these analyses were correct, and every one of these five reasons I have, I believe, shown conclusively in my book to be absolutely unsound. All these "analyses" are teeming with suggestion; in fact, Freud himself admits this. Here are his own words: "A psycho-analysis is not an unbiased scientific research, but just a therapeutic intervention. The physician gives in psycho-analysis every time to the patient the respective expectation-ideas by means of which he (the patient) shall be enabled to recognise that which is unconscious and to seize it, sometimes this is done more freely, sometimes less. Just as it happens, some cases require more help, others require less. Without such help no one can get on."[1] After this all argument appears really superfluous, for it shows that dream-interpretation is the *via regia* to the unconscious, not of the patient, as Freud says, but to that of the psycho-analyst, as I suggest. Dr. Riggall's statement that I have not employed the technique myself is an unwarranted assertion, for he would have found evidence to the contrary if he had read my book which he assumes to criticise. Why he persists to harp upon *abreaction* after the quotation from my book given in my last letter to you, if not for the purpose of side-tracking the discussion, I fail to see. As to Dr. Riggall's test-tube analogy reasoning, it suffers from the same defects as Freud's arguments of the same kind and of which I demolished nearly half a dozen in my book. I could easily turn the tables upon Dr. Riggall with this very argument, but I suppose your space is too precious.

I am, Sir, yours faithfully,

Shortlands, Kent, May 10th, 1924. A. WOHLGEMUTH.

WASTING DISEASES OF CHILDHOOD.

To the Editor of THE LANCET.

SIR,—In his comprehensive lectures on the Wasting Disorders of Early Infancy recently published in THE LANCET, Dr. L. G. Parsons makes the statement that xerophthalmia is a rare disease in this country, and mentions that in 13 years only 13 cases were seen at the Birmingham and Midland Hospital for Children. He contrasts this with the condition in Denmark, where he says "the disease has been observed much more frequently," without, however, giving figures.

As this statement may give a wrong impression of the actual incidence of the disease and of the significance of this incidence, I venture to submit the following considerations. Xerophthalmia is a rare disease even in Denmark. A Danish ophthalmologist, Dr. Olaf Blegvad, has collected all the cases of the diseases which have occurred in Denmark during the years 1909–20, and has discussed the importance of this disease in an important monograph of which a summary written by himself has appeared recently in the *American Journal of Ophthalmology*. The total number of cases of xerophthalmia observed in the whole of Denmark during the 12 years 1909–20 is only 445. The disease is, as he points out, an economic disease; it occurs only among the poorer classes. It is, therefore, not admissible to assume that the disease is rare or absent in this country because it happens to be infrequent in one particular locality. It is certainly more frequent in some parts of the country than Dr. Parsons's statement would lead one to believe. For in the fourteenth annual report of the school medical officer for the West Riding of Yorkshire County Council for the year 1921 one doctor, Dr. Tyrrell, discovered 19 cases in two years in one relatively small area. It is possible also that the disease in its mild form is not always recognised and merely regarded as a conjunctivitis. That was the case, for instance, in the previous outbreaks in an industrial school which I quoted in my recent lecture. And in his report on the Health of the School Child, in which not a single case of xerophthalma is reported, Sir George Newman quotes one authority who looks upon diseases of the surfaces of the eye merely as indicating lack of cleanliness.

---

[1] Sammlung kleiner Schriften zur Neurosenlehre, 3te Folge, Leipzig, &c., 1913, p. 88.

The importance which attaches to the occurrence of even a few cases of xerophthalmia is this. Xerophthalmia is not merely an affection of the eye, it is part of a general condition of malnutrition due to a deficiency in the fat-soluble vitamin-A, which manifests itself long before the eye disease appears by subnormal growth and weight, by anæmia, general debility, and by a diminished resistance to infection, especially infections of the respiratory tract. Xerophthalmia only sets in when the condition of malnutrition has reached its extreme stage. That means that the ill-effects of a vitamin-A deficiency manifest themselves long before the appearance of the eye affection.

The occurrence of a numerically small number of cases of xerophthalmia in Denmark is taken by Dr. Blegvad not as a measure of the extent of malnutrition, but as a danger-signal disclosing a widespread condition of malnutrition due to the fact that the substitution of margarine for butter among the poorer classes has deprived the latter of an adequate supply of vitamin-A. In this country, according to Sir George Newman's report, out of 700,000 school-children examined, 15,000 suffer from malnutrition and another 15,000 from anæmia, conditions which *may* be due to underfeeding with vitamin-A. In this country margarine has replaced butter among the poorer classes, and cases of xerophthalmia have been discovered in a relatively small area approaching the proportion found in Denmark. The inference seems obvious.

I am, Sir, yours faithfully,
W. CRAMER.

Imperial Cancer Research Fund, London, May 12th, 1924.

THE NARCOTIC ACTION OF PURE ETHER.

To the Editor of THE LANCET.

SIR,—In your issue of May 10th Prof. Storm van Leeuwen states that a 5 per cent. solution of methylethylketone in ether is too toxic to be safe as an anæsthetic agent, because some cats anæsthetised with it on two consecutive days developed hæmorrhages in various organs. As I have used various ketones as anæsthetics for four years (including methylethylketone), I venture to say that I disagree with him. It appears impossible to predict what will be the effect of drugs on man by direct analogy from animals. For example, monkeys very frequently die of pneumonia after the briefest ether anæsthesia, but we do not say that on this account its use is contra-indicated in man.

Before any work on ketones was published, the question of toxicity was thoroughly investigated, and I had anæsthetised over 250 patients with mixtures of various ketones ranging from 0·5 to 10 per cent. in pure ether. It was recognised at the outset that if any ultimate preparation was to have any value as an anæsthetic it must have a mortality-rate lower than 1 in 5000 administrations to compare with the modern techniques employing other drugs. As no toxic effects were observed in the dilutions mentioned above, I next tried a 50 per cent. ketone-ether mixture. This was unsatisfactory, as the mixture was not homogeneous and did not readily vaporise. Pure ketones were next tried with no added ether, and an extremely good anæsthetic resulted. None of these patients vomited at all or exhibited any other after-effects whatever, and the method was only discontinued because some difficulty was experienced in obtaining a suitable vaporiser. The apparatus used consisted of a perforated aluminium plate heated by a resistance coil and mounted in the top of a mask from a Hewitt's wide-bore inhaler. An adjustable pressure-fed drip-feed led the ketone mixture on to the hot plate and the temperature was regulated by a rheostat. This vaporiser required considerable attention to maintain it at a constant temperature, but I have no doubt that if anyone took the time and trouble to construct a thermostatically controlled apparatus this difficulty could be avoided. It seemed to us, however, that the simpler way was to incorporate the ketone mixture in a volatile base, such as pure ether, and thus effect vaporisation without employing heat.

All the ketones used in the above experiments were purchased direct from British and foreign chemical manufacturers, so there is no doubt that they were reasonably pure products. In view of the fact that toxic effects over a period of four years have been at any rate not more pronounced than with other anæsthetics, I suggest that the statement that the use of a 5 per cent. solution of methylethylketone dissolved in purest ether "would be criminal" is, to say the least, somewhat exaggerated.

I am, Sir, yours faithfully,
C. LANGTON HEWER.

Regent's Park, N.W., May 10th, 1924.

THE ARGYLL ROBERTSON PUPIL IN NON-SYPHILITIC CASES.

To the Editor of THE LANCET.

SIR,—The brief annotation on this subject in THE LANCET of May 10th seems rather to suppose the occurrence of the Argyll Robertson pupil apart from neurosyphilis as somewhat of a novelty and the apparent number of such cases as "disconcerting." As a fact, cases of this kind have been familiar to the neurologist for years and have often been recorded. There is abundant evidence of a clinico-pathological kind to associate the Argyll Robertson pupil with lesions in the vicinity of the superior colliculi, and this site, further, has been shown experimentally to be one in which by an appropriate lesion the Argyll Robertson phenomenon can be produced. In the *Journal of Neurology and Psychopathology* for May, 1921, will be found the whole of the subject elucidated at length, with numerous instances of non-syphilitic A.R. pupils. There the evidence pointing to the mesencephalic origin of the phenomenon in a large number of cases is marshalled. Later contributions to the subject substantiating the mid-brain localisations have appeared in the same journal in the numbers for August, 1922, and August, 1923, respectively.

I am, Sir, yours faithfully,
S. A. KINNIER WILSON.

Harley-street, W., May 10th, 1924.

DRIED MILK REGULATIONS.

To the Editor of THE LANCET.

SIR,—May I invite attention to the Public Health (Dried Milk) Regulations, 1923, which came into operation on May 1st. As a physician who has studied dried milk since its adoption in infant feeding after the National Conference on Infant Mortality in 1906, I suggest that these regulations challenge criticism. Dried milk is a distinct boon, especially in India where most of my life has been spent, and I can find nothing to indicate that the numerous varieties on the market showed such disparity in composition as to call for special legislation. It will be seen that the Ministry consider that milk powder containing only half or three-quarter cream should only be used "under medical advice." This is not the general opinion of pediatricians either in this country or on the Continent. Hutchison says: "Many young infants do very well on half cream dried milk and digest it better than preparations which contain more fat"; and in France half cream is the variety in general use. At a meeting of the Society of Pediatricians of Paris held a year or two ago to specially consider the use of this substance in infant feeding, it was stated, "full cream powder on account of the large amount of fat which it contains keeps badly. . . . Half cream powder is the variety in general use; it complies with most requirements and is the form of dried milk which is the subject of this discussion."

The new regulations place dried milk at some disadvantage as compared with the fresh product as they require a standard of 3·6 per cent. of fat, whereas the legal standard for wet milk is only 3 per cent. It would be interesting to know why there should be different standards for the same article in different forms, but this inconsistency falls into insignificance when we realise that these regulations only concern themselves with dried milks which are accepted by the profession as safe for infant feeding when breast feeding is impossible, whereas no restrictions whatever are placed on the sale of products which are positively dangerous in infant dietary. Infant foods may be classed under three headings—viz., Group 1 consisting of dried milk in various forms, Group 2 consisting of various forms of carbohydrate either malted or designed to be digested in the process of mixing, and Group 3 consisting of unaltered starch. Starch is not a substance which can be given with impunity to young infants, yet the whole of a large group of infant foods consist of this product *pur et simple*. Under the law these products can be sold without let or hindrance, although Hutchison describes one much-advertised product as follows: "A baked flour containing 3 per cent. of soluble carbohydrates, the remainder being starch. Recommended to be made with milk or water. Made with water is totally insufficient food."

The regulations deal with products which are no more harmful in hand feeding of infants than ordinary cow's milk. It appears to me that the Ministry has started legislation at the wrong end.

I am, Sir, yours faithfully,

R. J. BLACKHAM, M.D., M.R.C.P.Edin.,
late Hon. Surgeon to the Viceroy of India.

Harley-street, W., May 7th, 1924.

*** The Health Committee of the Middlesex County Council has recently received a complaint with reference to an infants' food sold as a proprietary article by a drug store in a poor district of the county, and which is stated to have a very large sale. The county analyst's report confirms the statement made that this food consists principally of starch, and lacks the essential constituents of a suitable food for infants. The Health Committee understands that the use of the food in question is doing a great deal of harm to infants who are fed upon it, but there does not seem to be any action which the Council can take under the Sale of Food and Drugs Acts. In 1914 the whole subject of proprietary foods containing large quantities of starch was dealt with in an exhaustive report to the Local Government Board by one of the medical officers of that department, who urged the necessity for legislation to give local authorities power to deal with foods similar to the one under notice. It is probable that but for the war this report would have been acted upon years ago. The Committee is of opinion that the matter should be dealt with by Parliament, and that local authorities should be given power to prevent the sale of harmful food for infants.—ED. L.

TUBERCULIN IN ASTHMA.

To the Editor of THE LANCET.

SIR,—A summary of Mr. Arjeff's results on the treatment of bronchial asthma with tuberculin has recently been recorded.[1] He found this treatment most disappointing. On the other hand, Storm van Leeuwen and Varekamp[2] seem to have had brilliant results. The number treated in both series is small, but even a few cases, when added to one's own observations, are helpful.

I submit, in all modesty, a theory as to the rationale of giving tuberculin in asthma. Dr. Langdon Brown[3] points out that the problems involved in asthma are psychical conditions, peripheral stimuli, foreign proteins, want of endocrine balance, all tending to produce vagotonia, and goes on to say: "I should like to call special attention to enlarged bronchial glands, especially in children, and to suggest that this may explain the liability of healed tuberculosis to excite asthma in susceptible subjects."

We know that children tend to be vagotonic and that, as a rule, they take tuberculin well. We also know that we must observe caution in giving tuberculin to sympathicotonics. The symptoms of active tuberculosis tend to be those of sympathicotonia, and the symptoms of tuberculin poisoning are those of active tuberculosis. I suggest, therefore, that tuberculin stimulates the sympathetic and so antagonises the action of the vagus, thus explaining why an overdose of tuberculin which, on this hypothesis, acts first as a sympathetic stimulant then as a depressant, can bring on an attack of asthma, and also explaining the rapid improvement obtained by van Leeuwen and Varekamp which I have also noted in my cases with the initial small doses.

Tuberculin, except in large doses, causes no disturbance in the non-tuberculous. It seems improbable that the minute doses used in asthma could have any effect whatever unless there be some tuberculous focus present. That such focus is present in some cases of asthma, though not detected by clinical methods, is probable—e.g., the enlarged bronchial glands referred to above. It is stated that two of Arjeff's cases were made worse, and that in nine the tuberculin did not have the slightest effect. These results so differ from those of van Leeuwen and Varekamp and from mine that I cannot but believe there is a fallacy somewhere.

In reading van Leeuwen and Varekamp's paper carefully one is struck by the following points: (1) the small number (4 per cent. only) of asthmatics who gave positive skin reactions to foods, &c.; (2) that persons who react strongly to food tests also give a strong Pirquet reaction; (3) that 30 out of 34 cases of bronchial asthma gave a positive reaction with tuberculin; (4) that very small doses were given and better results were obtained by keeping to these small doses; (5) that in most cases two or three doses of tuberculin were sufficient to cure, but that treatment was continued for two or three months; (6) that on two occasions an attack of asthma was produced by overdosing; (7) that a strong Pirquet reaction does not point to active tuberculosis.

When I turn to my own experience, which is but limited, I find: (1) that in cases in which a modified Pirquet reaction (1 in 10 O.T.) is negative no benefit is obtained from tuberculin unless there is other evidence of disease; (2) that in every case which reacted to tuberculin there was considerable relief of symptoms; (3) that in such cases relief is quickly afforded even after a single dose or two. Believing that tuberculin in some way stimulates the sympathetic and in this way probably liberates adrenalin, I have always begun with a small dose and cautiously increased it, reaching, in some cases, as much as 1 c.cm. of tuberculin.

Summary of the Results.—(*a*) Cases which reacted to tuberculin or who had obvious signs of tuberculosis,

[3] Roy. Soc. Med. Proc., January, 1923.

10—asthma apparently benefited or cured in all; (*b*) cases which did not react to tuberculin, 3—apparently no benefit in any. The following points are of interest: (1) the successful cases were mostly subsensitive to the tuberculin cutaneous tests—i.e., they reacted to dilutions of 1 in 10, but not to higher dilutions; (2) the blood pressure, generally speaking, was fairly high—130 or over; (3) in nearly all cases there was considerable fibrosis as shown by X rays.

My thanks are due to Dr. F. Hernaman-Johnson for X ray reports, and to Dr. H. A. Ellis for taking the tuberculin cutaneous reactions.

I am, Sir, yours faithfully,
F. E. Gunter, M.D. Edin.,

SIGNS OF INSANITY.

To the Editor of The Lancet.

Sir,—In view of the importance which we are nowadays told is to be attached to isolated facts, as indications of insanity, it may be of interest to some of your readers to consider the evidential value of the accompanying letter, which I recently received from a patient under my care. Does the letter, which is a perfectly grammatical and intelligible production, indicate insanity, and if so, why? One wonders what a jury would think about it. I should add that the enclosure is by no means the entire letter, but only its first sentence.

I am, Sir, yours faithfully,
York, May 7th, 1924. Henry Yellowlees, M.D.

[Enclosure.]

Dear Sir,—Your assistant, Dr. M., was in the gallery on my return thither to-day after my matutinal round, an hour or two of which had been incidentally devoted to the project of consuming as rapidly as possible, with the idea of obtaining a good blaze, some recalcitrant tree roots, laurel clippings, ivy leaves, and other rubbish of a vegetable character which had been, or was in process of being, wheeled into the manure compound, and to take up the "thread" I enquired from him, in the absence of an announcement, as to the upshot of the consideration of—to me—the most important item on your agenda for last Tuesday's Committee meeting, and I was half inclined—in view of what I at first conceived to be—and perhaps too hastily—either a breach of etiquette or business routine—to confide in him the details of the cogent, personal matter in the negotiation of which, metaphorically speaking at any rate, you might almost be regarded as my plenipotentiary; but on ascertaining from Dr. M. after sounding him as to the practicability of an interview that when he left you this morning there was a "string" of six or seven people awaiting an audience, I deemed it preferable to await developments and avail myself of his suggestion to write to you!

Donations and Bequests.—The late Sir Alexander Grigor Jeans, of Cheshire, editor and managing director of Liverpool newspapers, left by will £250 to the Liverpool Royal Infirmary; £100 to the Liverpool Northern Hospital; £100 to the Liverpool Southern Hospital; and £100 to the Birkenhead Borough Hospital.—By will the late Mr. Robert Pauling, of Kingston-on-Hull, Yorks, left £500 to the Hull Infirmary; £250 to St. Dunstan's Hostel; £200 to the Victoria Hospital for Children, Hull; £200 to the Hull Orthopædic Institute; £200 to the Hull and Sculcoates Dispensary; and £200 to the Hull Institute for the Deaf and Dumb.

Paddington Green Children's Hospital.—With an increase in the number of patients treated during the year, an expenditure which exceeded the income by £1339, and a debt at the bank of £13,500, the committee of this institution make an earnest appeal for additional financial support. The total number of in-patients treated in 1923, the year with which the report deals, was 869 as compared with 750 in the previous year, or an increase of 119; while new out-patients numbered 12,122, as compared with 11,498 in 1922, an increase of 624. The number of attendances in the out-patient department in 1923 was 43,731 in contrast with 39,778 in the preceding year—an increase of 3953. The average stay in hospital of the in-patients was, roughly, 14 days in both 1922 and in 1923, but the average cost per patient for this period was, in the latter year, reduced from £8 10*s.* 8*d.* to £7 8*s.* 10*d.* During the year 1923, 113 patients were sent to the Convalescent Home at Slough, where the average stay is 35 days, the cost per patient being a little over £2 5*s.* a week. Towards the cost of maintenance of these convalescents parents contributed a sum of £126.

Obituary.

SAMUEL GEORGE SHATTOCK, F.R.S., F.R.C.S.Eng.

Samuel George Shattock, Professor of Morbid Anatomy in the University of London, who died at Wimbledon on May 11th after six months' serious illness, will be mourned not only by his colleagues and pupils at St. Thomas's Hospital and at the Royal College of Surgeons of England, but by pathologists throughout the civilised world, for his reputation was international. Born in 1852, he was educated at University College School and entered University College, London, as a medical student in 1869, qualifying M.R.C.S. Eng. in 1874. In 1875 he was awarded the Liston gold medal at University College Hospital and became interested in descriptive pathology as early as 1876, when he began a catalogue of the surgical pathology of the museum at University College, London, under the supervision of Mr. Marcus Beck. In 1878 he started an original investigation on the reparative processes that occur in vegetable tissues, and in the same year began to outline the attachments of the muscles on a series of human bones, now permanently exhibited in the anatomical collection of the Museum of the Royal College of Surgeons. He was then elected as Curator of the Pathological and Anatomical Museum, University College. In 1881 Shattock became a Fellow of the Royal College of Surgeons of England. and in 1884 was appointed Curator of the Museum at St. Thomas's Hospital, London, so that his association with both these institutions extends over more than 40 years. In 1884 also he was elected on the Morbid Growths Committee of the Pathological Society of London, and the next year a member of the Council of the Society. At this time he started an optional class on surgical pathology at St. Thomas's, which in 1886 became an official class. These were the first classes in surgical pathology given in London, and in 1888, as newly-appointed lecturer in surgical pathology, Shattock delivered the first course of lectures on surgical

Professor Shattock.

pathology ever held in London. The next year he started work on a new pathological catalogue of the museum at St. Thomas's Hospital, a task which engaged much of his time until 1894, when it was completed. In this year he gave the Morton lecture on cancer at the Royal College of Surgeons, and in 1895, for the first time, a private short course on practical bacteriology at St. Thomas's Hospital.

Meanwhile Shattock's work in pathological research had attracted attention, and he had been made successively secretary and vice-president both of the Pathological Society of London and of the Pathological Section of the B.M.A. annual meetings, and an assistant editor of the *Journal of Pathology and Bacteriology*. He contributed papers chronicling an attempt to cultivate protozoa from malignant tumours, jointly with Sir Charles Ballance, and on the healing of incisions in vegetable tissues to the Royal Society, and was selected to write the article on General Pathology of New Growths in Sir Clifford Allbutt's "System of Medicine." Shattock became a member of the Council of the British Institute of Preventive Medicine (now the Lister Institute) in 1896, and the next year was made Pathological Curator at the Royal College of Surgeons, London, holding this appointment jointly with his posts at St. Thomas's Medical School. In 1899 he was made editor of the Transactions of the Pathological Society, and in the same year was appointed external examiner in pathology of the Victoria University (Manchester). In 1904 he was made examiner in pathology at the University of London, with Dr. Sidney Martin; this was the first occasion on which a separate examination was conducted by special examiners in pathology. In 1907 Shattock was elected first President of the Section of Pathology of the Royal Society of Medicine, and was also elected representative of the section on the Editorial Committee of this newly-formed Society, and a member of the Council. Prof. Shattock first gave lectures and demonstrations at the Royal College of Surgeons in 1909, when he delivered two Hunterian lectures on Certain Matters connected with Internal Secretion and Certain Matters Connected with Fat. At this period he began a new edition of the pathological catalogue, of the Royal College, with the aid of Mr. C. F. Beadles. He determined to make a special feature of the general pathology, and many specimens were transferred from the groups illustrating special pathology to that of general pathology. In 1910 he became President of the Section of Pathology at the meeting of the B.M.A. in July and was made a Fellow of University College, London. In 1913 he was made President of the Section of General Pathology and Pathological Anatomy at the International Congress of Medicine which met in London, and gave the introductory address. He spoke of the large proportion of scientific work which was unattended by positive results. This necessarily followed from the incalculable complexity of what was investigated, as contrasted with the limitations of the researching instrument—the investigator. The temptation to substitute conjecture and verbal formulæ for accurate knowledge, common to all workers, should, he said, be fought most strenuously, and by example as well as precept Shattock throughout his life taught this lesson. In 1916 he received the diploma of the Honorary Fellowship of the Royal Society of Medicine as a recognition of scientific work, and the next year was elected Fellow of the Royal Society of London. In the same year he was appointed to select, with the help of Mr. Beadles, specimens for permanent preservation from the large number of specimens of gunshot injuries received from the seat of the war, and in 1922 began recataloguing the specimens of special pathology at the Royal College of Surgeons, a work which has not been completed at the time of his death.

Shattock's academic activities and his work in descriptive pathology might well have fully occupied his professional life; and, indeed, it is probable that he will be best remembered as a great pathological anatomist. But he also devoted considerable attention to the study of cancer, and it was his habit, whenever possible, to apply the experimental method to the problems of morbid anatomy. Further, he was one of the earliest students and teachers of bacteriology in this country. His influence on the surgical pathology of our time is almost impossible to assess, for besides the work which appears over his name very many of the surgical monographs published at the present time bear willing evidence to the unofficial help and inspiration he has given to the writers. Always a reserved man, few among his colleagues had any part in his private life. His interests were always those of the student, and for upwards of 40 years every moment he could spare from his professional work were spent in compiling and elaborating notes on religion and kindred subjects which, by his wish, will be published posthumously.

A fellow-pathologist writes:—"Although it has been generally known that the state of his health has for some time been such as to give rise to grave anxiety, the news of Shattock's death must inevitably come as a severe shock. For so many years he has occupied such a prominent place in scientific medicine that it is scarcely possible to realise that his life's work is really at an end. As a teacher of pathology few men have played a more important part. It is difficult for the modern student to visualise a curriculum which contained no recognised teaching in pathology, and it is well for us to realise that had it not been for the devotion and enthusiasm of such men as Shattock the study of scientific medicine in London could never have reached its present level. Above everything else a morbid anatomist, a great part of his life's work was given to the pathological museums of St. Thomas's Hospital and the Royal College of Surgeons; the pathological collection of the College is itself a monument to his untiring energy and skill. The story of Shattock's life is intimately bound up with that of the Pathological Society of London and the Royal Society of Medicine. For close on half a century he was one of the mainstays of the Society. Though of late years he rarely attended the laboratory meetings, he was scarcely ever absent from the more formal meetings in the old days in Hanover-square and later in Wimpole-street. The actual bulk of his contributions to the Transactions on a great variety of subjects must be very considerable, but possibly of even greater value were his contributions to debates and his personal influence. Himself a most accurate worker and a man of great learning, he insisted on a high standard, and though from time to time his junior colleagues may perhaps have realised with some chagrin that there is indeed nothing new under the sun, his criticisms were always stimulating. And no man ever applied to him for help and assistance in vain. A great student, a great teacher, and an upright man, Shattock made for himself a place which it is doubtful if another can ever fill."

The following appreciation is from a colleague at the Royal College of Surgeons of many years' standing:—

"The death of Prof. Samuel Shattock removes a familiar and affectionately regarded figure, not only from the Museum and Library of the Royal College of Surgeons and from St. Thomas's, but also from Wimbledon. Seeing this remarkable old savant in the costume of a bygone generation of medical men, the fine musing face touched at times with a kindly smile under the broad-brimmed top hat of a shape that defied all changes of fashion, the highly individual ambling gait, the immemorial black bag of ample dimensions—seeing these, people familiar with his aspect in their daily walks have wondered who "the old professor" might be, and have been justly rebuked and surprised when informed that he was one of the acknowledged chiefs of the world of science, and especially of his own world of pathological anatomy. He had, indeed, accomplished an infinity of work on the lines of the Hunterian tradition at the

Royal College of Surgeons, where his best monument is Room III., on the floor of which, during 1923, he had finally arranged the magnificent collection of specimens illustrative of the principles of pathology. Jointly with Mr. Cecil Beadles, Shattock had begun to select, arrange, and catalogue specimens as long ago as 1910, ‘thus laying the basis of the scheme which they have now brought to a most successful issue.’ The words quoted are from Sir Arthur Keith’s museum report for 1923, where a full and interesting account of Shattock’s recent work in general pathology will be found. Death intervened before he could finish his last great undertaking—the arrangement of the Section of General Pathology. An ardent worker, a man of the greatest acumen and scientific learning, Shattock remained much of a mystery to the colleagues about him. It has taken one of them half a lifetime to find out that he knew all the names of the Derby winners for some 100 years, that he was a devotee of cricket, never missed an opportunity of going to see a match at Lords, and was an authority on cricket scores; also that he was very musical and an excellent executant, and a very kindly genial gentleman, both at his own Wimbledon home and in his museum laboratories.”

Prof. Shattock leaves a widow, one daughter, and three sons, of whom one, Mr. C. E. Shattock, is surgeon to the Royal Free Hospital.

GEORGE HENRY OLIVER, L.R.C.P. LOND.

Dr. G. H. Oliver, consulting ophthalmic surgeon to the Royal Eye and Ear Hospital, Bradford, died recently at his residence in Bradford after a long illness. Born in 1861, he received his education in Leeds and Vienna, and qualified in medicine in 1885 as L.S.A. and M.R.C.S. Eng. Three years later he obtained the L.R.C.P. Lond. He laid the foundations for successful ophthalmological work at the outset of his career; after qualifying he held the position of demonstrator of anatomy in the University of Leeds, thus acquiring a thorough knowledge of general anatomy, and subsequently in Vienna he devoted himself to the study of the eye. On his return to England he began his professional life in general practice first at Clayton and shortly afterwards in Bradford, but he gradually limited his work to ophthalmology alone and was appointed hon. surgeon to the Bradford Eye and Ear Infirmary, a position which he held until 1921, when, at the age of 60, he was appointed to the consulting staff.

Dr. Oliver kept himself abreast of the latest developments in his specialty and, while connected with the Bradford Infirmary he frequently obtained leave to visit centres where special original work was being done in order to get first-hand information. When the Oxford Ophthalmological Congress was founded in 1909 he was one of its original members. In 1913 he gained the Oxford Diploma in Ophthalmology and remained for a time as lecturer in ophthalmology at Oxford University. He also held appointments as ophthalmic surgeon to the Health Committee of Bradford City Corporation and to St. Luke’s Municipal Hospital, Bradford. During the war he was officer in command of No. 84 Ophthalmic Centre War Hospital, and was ophthalmic surgeon to the Bradford War Hospital. In 1922 he was President of the Bradford Division of the British Medical Association. Dr. Oliver contributed many articles to medical journals on his own subject.

A colleague writes of him: “An indefatigable worker, Dr. Oliver was simple in his tastes and lived for his profession. He was a good pathologist, examining every case with meticulous care, and as a refractionist he was exceptionally quick. His love of reading bore fruit in the excellent collection of the latest English and German ophthalmological works in the library of the Bradford Infirmary, where he acted as curator. He was a great favourite with his patients no less than with his medical friends and colleagues, and he will be greatly missed.”

DAVID NEWMAN, M.D., C.M., F.R.F.P.S. GLASG.

Dr. David Newman, hon. consulting surgeon to the Glasgow Royal Infirmary, died recently at sea in his seventy-second year. A son of Edward Newman, M.D., Fleet Surgeon, R.N., he was educated at the Glasgow Academy, and proceeded to the study of medicine at Glasgow University, where he qualified M.B., C.M. in 1878. He continued his medical studies at the University of Leipzig, and in 1881 became a Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow, gaining his M.D. Glasg. with high commendation two years later. Dr. Newman devoted himself early in his career to the special branch of genito-urinary surgery, on which he published in the course of his life-time many valuable treatises, both in book form and as articles in various surgical manuals, medical encyclopædias, and medical journals. Of his life and work a friend and colleague sends us the following account:—

> About 35 years ago Dr. Newman first demonstrated the cystoscope to the writer, an instrument regarded then as more or less a scientific toy, but shown by the demonstrator to be an instrument of precision. At that time the surgery of the urinary apparatus was ill-defined and crude: the work of Newman helped very materially to make diagnosis more exact, to lay foundations for certitude in operative procedure, and to widen the range of knowledge in anatomy and physiology. Newman worked for some years along other lines before finding his true métier. About 1880 he was pathological chemist in the Western Infirmary and assistant to Dr. Joseph Coats, pathologist to the infirmary, and at that time he realised the essential value of what we now call chemical pathology. Some years later he became pathologist in the Royal Infirmary, where he carried out his investigations into the malformations and malpositions of the kidneys. He next adventured in the region of diseases of the nose and throat, becoming in 1890 surgeon to the throat department of the infirmary. The outcome of this period of his career was the volume on Malignant Disease of the Throat and Nose. When, in 1893, Dr. Newman was appointed surgeon to the Royal Infirmary of Glasgow, he was already a man of some note, possessed of varied experience and a basic training in pathology. He became rapidly known as an authority on the surgery of the kidney and published several works on its surgical diseases. To a large extent his work was pioneer work and demanded originality of outlook and pertinacity in investigation. His reputation was considerably beyond the confines of his own school, and he was recognised as an authority in the schools abroad—this recognition taking practical form when he was invited to open a discussion on the surgery of the kidney at the annual meeting of the British Medical Association in 1908, and to become vice-president of the Urological Section of the International Congress in London in 1913. He was visiting surgeon to the Royal Infirmary for 21 years. There were but few students in the Royal in those days before the war, but when opportunity offered he proved himself to be a good teacher and a lucid, forceful lecturer. He was probably more at home demonstrating to the medical societies in Glasgow, where his audiences were men of experience in practice.

Dr. Newman was a man of good friendship within his own circle, and his death adds yet another to the recent losses in the surgical world of Glasgow.

JOSEPH HENRY WILKS, M.B., B.CH. CAMB.

BY the lamented death of Dr. Wilks, from encephalitis lethargica, at the age of 58 years, the medical profession of Sheffield has suffered a great loss. The eldest son of Mr. Edward John Wilks, principal of Messrs. Wilks Bros., ironmongers, he received his early education at the Wesley College, Sheffield, going on to Caius College, Cambridge, where he took his degree in 1887. His medical training began at the Sheffield School of Medicine, was continued at Cambridge and St. Bartholomew’s Hospital, London. After graduating in medicine in 1891, he held appointments at the West London and Bethlem Hospitals, and was clinical assistant at the Royal Ophthalmic Hospital. In 1898 he succeeded Dr. J. Black Milne on the honorary staff of the Sheffield Children’s Hospital, to which he devoted self-denying service over many years. During the war he rendered able help at the Wharncliffe War Hospital.

A medical friend writes :

"Dr. Wilks was a general practitioner of the best type. Upright, conscientious, and unselfish, he carried on his work amongst the people for over 30 years without any thought of personal aggrandisement or self-glorification. Those of us who had an opportunity of seeing something of that work knew the care and trouble with which every case was always investigated and watched, and the amount of thought and attention which he gave to every detail which might relieve or aid his patient. Although fully capable of so doing had he desired it, Wilks took little or no active or public part in the medical or civic affairs of the city. By nature he was modest and retiring, and was contented and happy in carrying out thoroughly and well 'the daily round, the common task.' His end came as he would have wished, whilst still in the midst of full work."

Dr. Wilks was taken ill one evening whilst making a professional call, and although at first the symptoms did not appear to be of a dangerous character so that he was able to leave home for what all hoped was a convalescent holiday, developments of a serious kind supervened, and the end came with tragic suddenness. He leaves a widow and two daughters.

THE LATE DR. H. A. BULL:

AN APPEAL.

WE have received an appeal on behalf of the widow and three children of the late Dr. Bull of Great Haywood, who, by his untimely death, have been left extremely ill-provided for. For some three years Dr. Bull suffered from abdominal disease requiring several operations and long absences from duty, and it is estimated that the capitalisation of all his resources will realise less than £200 per annum. We set out briefly last week Dr. Bull's services to the medical profession and to the community. He was hon. treasurer for many years of the Staffordshire Panel Committee, a member of the County Council and many of its committees, a member of the Conjoint Tuberculosis Board and of the County Insurance Committee ; on all of which he worked in the interests of his fellow practitioners. Dr. W. D. Carruthers, county medical officer of health, has agreed to act as hon. treasurer to the fund, and subscriptions should be sent to him at Martin-street, Stafford. The appeal is signed by Dr. T. Ridley Bailey, chairman, and Dr. George L. Lefevre, secretary of the Staffordshire Panel Committee.

THE LATE DR. R. GRAY.—Dr. Robert Gray, of Armagh, died on April 25th, aged 79. Educated at Armagh School and at the schools of the Royal College of Surgeons in Ireland, he qualified L.R.C.S.I. in 1865, two years later he obtained the L.R.C.P. Edin., and subsequently the L.S.A. Lond. In 1872, a year previous to obtaining the L.R.C.P.I., Dr. Gray was appointed medical officer of Armagh dispensary district, a position which he held for some 43 years when he was succeeded by his eldest son, Dr. H. A. Gray. He also enjoyed an extensive general practice. He became a Fellow of the Royal College of Physicians of Ireland in 1895, and Sheriff for County Armagh when he retired in 1915. He was president of the North of Ireland Branch of the British Medical Association in 1897–98. He was also president of the Armagh Natural History and Philosophical Society, and at one time president of the Irish Medical Association. He was an active Freemason, and took a prominent interest in the Church.

THE LATE DR. J. A. FRASER.—James Alexander Fraser, L.R.C.P. Lond., who died on May 8th in his seventieth year, was a well-known medical man in Romford, Essex. He was a member of a distinguished Highland family, was born in Mauritius, and educated at Blackheath and Merton College, Oxford, taking his medical training at Guy's Hospital. During his student days he was a noted Rugby football player. Over 40 years ago he set up in practice at Romford, and for 35 years he held the office of medical superintendent at the Romford Poor-law Institution. He was also consulting surgeon to the Victoria Cottage Hospital for many years. Dr. Fraser was highly esteemed and respected in the neighbourhood, and his death is keenly felt by the community.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Poor-law Reform.

BEFORE the third reading of Local Authorities (Emergency Provisions) Bill on Monday, May 12th, some discussion took place as to the Government's attitude in regard to Poor-law reform. Mr. GREENWOOD (Parliamentary Secretary to the Ministry of Health) stated that communications were now passing between the three parties with the object of bringing about a conference between them in order that so far as practicable an agreed measure might be reached. In the opinion of the Government that was a speedier and on the whole a more desirable method of procedure than that of a Royal Commission or of a Departmental Committee. If the leaders of the various parties could agree to a conference the Ministry of Health would put before it definite proposals both as to procedure and policy.

HOUSE OF COMMONS.

WEDNESDAY, MAY 7TH.

The Insured Population.

Sir THOMAS ROBINSON asked the Minister of Labour the number of men, women, boys, and girls, respectively, insured under the National Health and Unemployment schemes, respectively, in 1913 and at the latest possible date.—Mr. THOMAS SHAW replied : The following are the available figures for Great Britain :—

Year.	Health insurance.			
	Men.	Boys (16–18 years).	Women.	Girls (16–18 years).
1913	9,645,000		4,005,000	
1923	10,200,000		4,800,000	
	Unemployment insurance.			
1913	2,250,000			
1923	7,830,000	540,000	2,500,000	380,000

At the date of the last valuation of Approved Societies (December, 1918) males and females between the ages of 16 and 18 years insured under Health Insurance scheme were 6 per cent. and 10 per cent., respectively, of the total numbers of males and females. In 1913 those insured against unemployment consisted almost wholly of males.

Washington Maternity Convention.

Mrs. WINTRINGHAM asked the Minister of Health whether he intended that the terms of reference of the Royal Commission on National Insurance would allow for consideration of the possibility of the ratification by this country of the Washington Maternity Convention of the International Labour Office.—Mr. WHEATLEY replied : I think the terms of reference given in my reply to the hon. Member for West Woolwich on May 1st would enable the recommendations of the Washington Maternity Convention to be considered as regards applicability to the insured population of the country.

Hygienic Qualities of Milk.

Mrs. WINTRINGHAM asked the Minister of Health whether the reports of his inspectors showed that the public could rely on the high hygienic quality of the large quantities of milk described on sale as nursery, invalids, or guaranteed ; and, if not, whether he would consider how the public might be safeguarded in the matter.—Mr. WHEATLEY replied : According to the information in my possession the answer to the first part of the question is "No." I will consider what steps it may be practicable to take to safeguard the public in this matter, but in the meantime I think the consumer would be well advised not to place too much reliance on descriptions and designations implying special hygienic qualities other than those authorised by the Milk (Special Designations) Order.

Salaries of Public Health Nurses.

Mrs. WINTRINGHAM asked the Minister of Health whether he was aware that many local authorities were paying to trained nurses engaged in public health work salaries as low as £130 per annum ; and whether he would take steps to ensure them an adequate salary, in view of the importance of health-visiting, in the prevention of infant mortality, and the long period of training and other qualifications which candidates for these appointments were expected to hold.—

Mr. Wheatley replied : According to the information in the possession of my department, payment of a rate of salary as low as £130 per annum is exceptional. I fully appreciate the importance of the work of health visitors, and the question of their salaries will continue to engage my attention.

Training Centres for Blind Persons.

Mr. Graham White asked the Minister of Health the number of workshops, hostels, and training centres for blind persons which had been opened since the Blind Persons Act, 1920, came into operation.—Mr. Wheatley replied : Since the Blind Persons Act, 1920, came into operation six new workshops have been opened and one is now in course of erection. Considerable extensions have been made or are in progress in connexion with eight existing workshops. Three new hostels for blind workers have been opened and one extended. Training centres are under the control of the Board of Education, but I am informed by my right hon. friend that the Board have recognised 12 new centres, eight new hostels, and extensions to two centres for training purposes.

Spirochætosis in Scotland.

Mr. Clarke asked the Under Secretary to the Scottish Board of Health if he was aware that there had been another outbreak of spirochætosis (rat-bite disease) in the same colliery in East Lothian ; in view of this, would he take steps to institute a public inquiry so as to give assurance to the miners employed in that district ; and was he aware that in one of the pits a section was stopped, with the result that no outbreak had been reported as having taken place since the date of stoppage.—Mr. Adamson (Secretary for Scotland) replied : I am aware that a fresh case is being treated in the Royal Infirmary, Edinburgh. I am having full inquiry made as to the circumstances of the outbreak, and when I have received the report I shall consult with the Secretary for Mines as to the expediency of holding a public inquiry. I have no information as to the last part of the question.

Cost of Medical Benefit Bill.

Mr. Masterman asked the Chancellor of the Exchequer how much Government grant would be required by the operations of the National Health Insurance (Cost of Medical Benefit) Bill ; how much of the amount required for this year was provided in the Civil Service Estimates ; and what would be the total cost of this national expenditure in a normal year.—Mr. W. Graham (Financial Secretary to the Treasury) replied : The National Health Insurance (Cost of Medical Benefit) Bill is estimated to involve an additional charge on the Exchequer of £392,000 in a normal year, but in the current year Supplementary Estimates will be presented in due course to provide £490,000 for the period of 15 months from Jan. 1st, 1924, to March 31st, 1925, no provision having been included for this purpose in the current Estimates.

Pasteurised Milk Regulations.

Mrs. Wintringham asked the Minister of Health whether he was aware that a large part of the milk sold as raw milk in our large cities had been pasteurised or otherwise treated by heat ; and whether he was prepared to take steps to ensure that purchasers might know whether their milk had been so treated.—Mr. Wheatley replied : Yes, and, while I am doubtful whether it will prove practicable to take effective steps in the direction suggested, I will consider the hon. Member's proposal. I am hopeful that the provisions of the Milk (Special Designations) Order, 1923, as to the use of the term " pasteurised " may contribute to the enlightenment of consumers and lead to the disuse of unapproved processes.

Thursday, May 8th.

Hospital Observation of ex-Service Men.

Captain Ramage asked the Minister of Pensions what regulations, if any, were now in force whereby disabled ex-Service men were placed in hospital for the purpose of observation ; what was the object of this period of observation ; and was any compensation paid to the men concerned in cases where they had suffered financial loss through loss of time while under observation.—Mr. F. O. Roberts replied : In exceptional cases it is the practice to admit a man to hospital for medical observation with a view to the proper determination of his case. If the disability has been accepted by the Ministry as due to or still aggravated by service full treatment allowances for a man and his family are paid ; in other cases allowances are paid in respect of his family.

Schools for the Deaf.

Mr. Graham White asked the President of the Board of Education the present accommodation in the certified special schools for the deaf, and the approximate number of deaf and dumb children in the country.—Mr. C. Trevelyan replied : The present accommodation in certified special schools for the deaf is 4582. The approximate number of deaf children in the country (including those who are partially deaf) based on returns furnished by local education authorities in respect of the year 1923 is 5700.

Medical Examination of Young Persons in Factories.

Lieut.-Colonel Fremantle asked the Secretary of State for the Home Department when the report was likely to be published of the committee appointed to inquire into the working of the provisions of the Factory and Workshops Acts for the medical examination of young persons as to their fitness for employment in factories.—Mr. Henderson replied : This report, which I have just received, will be presented at once to Parliament, and copies will be available, I hope, by the end of next week.

Dissection of a Body at Cleator Moor.

Mr. Gavan-Duffy asked the Secretary of State for the Home Department if he was aware that since the unlawful dissection of the body of J. M. Ashton at Cleator Moor, and the removal of the deceased man's brains without the widow's knowledge or consent, an application had been made by the legal representatives of the insurance company for a further examination, and, as the widow had withheld her consent, the insurance company now refused to undertake the cost of giving Christian burial to the part of the man's body unlawfully abstracted ; and would he submit the matter for the consideration of the Public Prosecutor with the object of proceedings being taken against those concerned.—Mr. Henderson replied : As this case contains some element of doubt as to the legal position, I propose to send the information in my possession to the Director of Public Prosecutions for his consideration.

Final Pension Awards.

Mr. Ernest Brown asked the Minister of Pensions if he would make any statement as to the final awards of Service men's pensions, and especially as to the problem of recurring diseases and ailments.—Mr. F. O. Roberts replied : Cases of recurrent ailments are met by the provision of medical treatment, with the grant of allowances if necessary. As regards cases in which it is shown that an award was erroneously declared final at the time it was made owing to a definite error of fact or judgment, I am glad to be able to assure the hon. Member that cases of this kind are now, in fact, being put right by the Ministry, and the correct award, whether final or conditional, made in lieu of the award which had erroneously been made final. Where a man claims to need treatment on account of his condition his case will be considered if as a result of medical treatment and observation error is discovered. Such claims go in the ordinary course through the local offices of the Ministry.

Monday, May 12th.

Medical Services in India.

Mr. Snell asked the Under Secretary of State for India whether he was aware that the recommendations of the Medical Services Committee were forwarded by the Government of India to the Secretary of State for decision some two years ago ; that no decision had yet been given by the Secretary of State for India, especially about the transfer of certain appointments ordinarily held by the Indian Medical Service officers to the provincial medical services in the various provinces ; that the question regarding medical research and the reduction of the military assistant surgeons and sub-assistant surgeons, forming part of the recommendations, was still undecided ; and whether, in view of the protests made lately in the Indian Legislative Assembly, he would undertake to expedite his decision.—Mr. Richards replied : It has been found impossible to adopt the fundamental proposal of the Medical Services Committee—i.e., the creation of a single medical service in India. I am sending the hon. Member a copy of a paper showing the extent to which civil posts are now reserved for Indian Medical Service officers in the provinces. With the addition of posts under the Central Government these number 333, as compared with 380 recommended for reservation by the Committee and 422 before the war. In the interests of economy the research service has been reduced to a skeleton cadre of six posts, all held by Indian Medical Service officers. In the case of military assistant surgeons no question of reservation arises, and the provincial authorities are, I believe, in some cases effecting reductions. In regard to sub-assistant surgeons I am not clear what information the hon. Member desires.

Pensioners and Medical Treatment.

Mr. Ernest Brown asked the Minister of Pensions whether his attention had been called to the fact that many ex-Service men who no longer enjoyed any pension were in receipt of treatment and received treatment allowances on account of the fact that their illness was consequent on service; and whether he was prepared to allow such men to re-open their claim to pension, the receipt of which in many cases would tend to prevent the recurrence of the illness which entitled them to treatment and treatment allowances.—Mr. J. W. MUIR (Parliamentary Secretary to the Ministry of Pensions) replied: I am glad to say that comparatively few of the men who have received final awards of the class referred to are, according to my information, in receipt of medical treatment. The need of treatment in consequence of temporary fluctuation of condition does not necessarily indicate that the final award made was erroneous, though where it is demonstrated, as a result of treatment, that serious error has occurred, the case will be put right in accordance with the procedure indicated in the answer which my right hon. friend gave the hon. Member on the 8th inst.

The White Lead Convention.

Sir PHILIP LLOYD-GREAME asked the Home Secretary whether it was the intention of the Government to ratify the White Lead Convention; and, if so, whether, and on what occasion, the Government proposed to obtain the approval of the House of Commons to such ratification.—Mr. DAVIES (Under Secretary for the Home Office) replied: The Government have introduced the Lead Paint Bill with the express purpose of giving effect to the provisions of the draft convention, and if Parliament accept the Bill and pass it without any amendments inconsistent with the Convention, it is proposed to ratify the Convention.

Retirement of Coroners.

Brigadier-General SPEARS asked the Home Secretary whether there was any retiring age for coroners; and, if not, how many coroners there were over the age of 75.—Mr. DAVIES replied: The answer to the first part of the question is in the negative. I have no information as to the age of coroners now holding office.

Clearance of Slum Areas.

Captain REGINALD TERRELL asked the Minister of Labour whether any towns were availing themselves of the Government subsidies hitherto sanctioned by the House to clear and rebuild on slum areas.—Mr. WHEATLEY replied: 57 local authorities have submitted schemes for the improvement of insanitary areas on the basis of financial assistance provided either under the Housing, &c., Act, 1919, or the Housing, &c., Act, 1923. In addition, about 40 local authorities have schemes in course of preparation or under consideration.

TUESDAY, MAY 13TH.

Conditions of Asylum Workers.

Mr. HORE-BELISHA asked the Minister of Health whether the proposed Royal Commission to inquire into the Lunacy Laws would be empowered to inquire into the hours and conditions of work of asylum workers; and, if so, whether he would consider the advisability of giving representation to asylum workers on the Commission.—Mr. GREENWOOD (Parliamentary Secretary to the Ministry of Health) replied: It is not proposed to ask the Royal Commission to inquire into the hours and conditions of work of asylum workers. The Departmental Committee on the Nursing Service in Mental Hospitals which is now sitting will, I understand, report on the question of hours for nurses.

CASSEL HOSPITAL FOR FUNCTIONAL NERVOUS DISORDERS.—The second annual report of the Cassel Hospital for Functional Nervous Disorders deals only with those patients who were discharged during 1921 and 1922, in order that late results of treatment may not be ignored. During the period under review 95 patients were discharged from the hospital; since 13 of these were in the hospital twice, the report deals with 182 individuals. Of these 113 suffered from one or other form of psychoneurosis, 4 were drug addicts, 47 suffered from a psychosis, 13 from organic disease, and 5 were unclassified. Among the first group, 29 state that they are now quite well, and 56 are considerably better; 3 state that they are no better, but are at work; 4 are better, but do not attribute the improvement to treatment in this hospital; 15 report that they are no better, but of these cases it is said that none was ever very promising. The results in the other groups are reported with the same fairness and care, most of the information being given in tabular form. The great importance of taking the patient's history in minute detail is emphasised. Future reports from this excellent institution will be awaited with interest, since the method of making them serial by the addition of a further report on the cases dealt with in the previous year (in this case 1921) must add greatly to the value of the records.

Medical News.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An extraordinary Comitia of the College was held on May 8th, Sir Humphry Rolleston, the President, being in the chair. The gentlemen elected to the Fellowship at the last Comitia (THE LANCET, May 3rd, p. 930) were admitted as Fellows and gave their faith to the College.

Licences to practise physic were granted to the following candidates who had passed since the last Comitia:—

James Carver, Cork and London; Margaret Corner, London; Horatio A. Cowan, Univ. Coll.; Howard S. Edwards, St. Andrews and St. George's; Dorothy E. Galbraith, Royal Free; Hyman Hamilton, Cardiff and London; Richard F. L. Hewlett, King's Coll.; Violet E. M. Mizen, Doris E. O'Doherty, and Margaret Swete, Royal Free; Lewis J. Watkins, Cardiff and St. Thomas's; and Muriel M. Yates, St. Mary's.

Diplomas in Public Health were granted, jointly with the Royal College of Surgeons of England, to the following candidates:—

Joseph D. Benjafield, Victoria E. Brander, Bernard Broadbent, James A. Cruickshank, Donald Davidson, Eric Hardy, John Hughes, Leslie M. Jennings, Dattatraya Ganesh Kotibhaskar, George Macdonald, Balaram Harischandra Madan, John A. Manifold, Don Swithin Merl Emmanuel Perera, Douglas Reynolds, Margaret M. Sands, Harbans Singh, Victor A. T. Spong, Marjorie P. Taylor, Edith I. Thornley, Ernest W. Wade, Lionel E. H. Whitby, Samuel J. Woodall, and Caroline I. Wright.

After some discussion it was resolved that candidates for the Membership be informed that the languages are not compulsory, but that credit will be given to those who show knowledge in these subjects.—A letter was received from Prof. C. Achard notifying the College of a lecture to be given at the Académie de Médecine to celebrate the tercentenary of the birth of Sydenham and inviting the College to send a representative. The Treasurer was nominated.—It was left to the President to nominate a representative of the College at the Congress of the Royal Institute of Public Health to be held at Bordeaux.—A letter was read from Prof. K. F. Wenckebach returning thanks to the President and Fellows for his reception at the recent lecture given by him before the College.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At an ordinary meeting of the Council of the College held on May 8th, Sir John Bland-Sutton, President, in the chair, Dr. Arthur Longley Whitehead, senior ophthalmic surgeon, General Infirmary, Leeds, was introduced, and after signing the by-laws was admitted a Fellow. Mr. John Howell Evans was introduced and was handed an honorarium, together with a certificate recording the Council's appreciation of the merits of his essay on the Pathology and Treatment of Malignant Diseases of the Testicle for the Jacksonian prize for 1923. Mr. William Warwick James was introduced and was handed the "John Tomes" prize, together with a document declaratory of the award, for his scientific work on the eruption of teeth, orthodontics, and the pathology of dental caries. Miss Pera Rosaline Cecilia Crawford, London School of Medicine for Women, having been introduced, signed the Roll of Begley Students, and received the first year's payment for her studentship, together with a document certifying her appointment as Begley student for three years.—Sir Cuthbert Wallace, K.C.M.G., surgeon to St. Thomas's Hospital, was re-elected a member of the Court of Examiners for a period of five years.

Diplomas of Member were conferred upon 169 candidates (137 men and 32 women) who have passed the requisite examinations and have complied with the by-laws of the College. The names and medical schools of the successful candidates were given in THE LANCET of May 10th (p. 979) with the exception of J. Carver, Cork and London, and Doris E. O'Doherty, Royal Free.

Diplomas in Public Health were conferred (conjointly with the Royal College of Physicians of London) upon 23 candidates.

The Licence in Dental Surgery was conferred upon Arthur Stuart Daniels, Guy's Hospital.

The Jacksonian prize, value £18 10*s*., will be awarded in 1924 for a dissertation on the Pathology, Diagnosis, and Treatment of Œsophageal Obstruction, and in 1925 for one on the Pathology and Treatment of Lymphadenoma (Hodgkin's disease). Candidates must be Fellows or Members of the College, not members of the Council. The number and importance of original facts will be considered principal points of excellence. The dissertations are to be delivered before the last day of the year, addressed to the Secretary at the College.

SOUTH LONDON HOSPITAL FOR WOMEN.—The new wing at the South London Hospital, South Side, Clapham Common, S.W., will be opened by the Duchess of York on May 22nd at 3.30 P.M.

TUBERCULOSIS SOCIETY.—An ordinary meeting of this society will be held to-day, Friday, May 16th, at the Margaret-street Hospital, Margaret-street, London, W., at 8 P.M., when Mr. Frank Kidd will read a paper on Tuberculosis of the Genito-Urinary Tract.

ROYAL SANITARY INSTITUTE.—The thirty-fifth Congress of the Institute will be held at Liverpool from July 14th to 19th. Lord Salisbury, as President of the Congress, will deliver his address at the inaugural meeting in the St. George's Hall on July 14th, at 8.30 P.M.

CHELSEA HOSPITAL FOR WOMEN.—A dinner will be given at the Mansion House on May 21st, the Lord Mayor presiding, to assist in raising the sum of £20,000 required by the hospital for the completion of a nurses' home, and to enable the council to open the "paying wards" at a very moderate charge. Donations may be sent to the Secretary at the hospital, Arthur-street, S.W. 3.

UNIVERSITY OF LONDON.—A public lecture on Sir Thomas Browne, Author of the Religio Medici: His Skull and Portraits, will be delivered by Miss M. Tildesley, research assistant, Royal College of Surgeons of England, on Tuesday, May 20th, at 5.30 P.M., in the Applied Statistics Theatre, University College (Gower-street entrance). The lecture, which will be illustrated by lantern slides, is open to the public without fee or ticket.

INTERNATIONAL SOCIETY OF PUBLIC HEALTH OFFICERS.—The provisional committee elected to draft the constitution and rules of this Society consists of Dr. Saimon (France), Dr. Grimani (Italy), Dr. Breger (Germany), Prof. Wladimiroff (Russia), Dr. Tubiasz (Poland), Dr. Pareja (Ecuador), with a representative of Great Britain to be nominated by the Society of Medical Officers of Health.

LONDON INTER-COLLEGIATE SCHOLARSHIPS BOARD.—Six medical entrance scholarships and exhibitions of an aggregate total value of £630, tenable in the Faculty of Medical Sciences of University College and in the medical schools of University College Hospital, the London Hospital, and the London (Royal Free Hospital) School of Medicine for Women, will be offered. The examination will commence on June 24th. Full particulars and entry forms may be obtained from the Secretary of the Board, Mr. S. C. Ranner, M.A., the Medical School, King's College Hospital, Denmark Hill, London, S.E. 5.

THE annual dinner of the Federation of Medical and Allied Services has been postponed to Friday, June 20th, at 7.15 P.M., to suit the convenience of the Prime Minister and other official guests who will be present. The dinner will be at the Langham Hotel, London, and Sir Berkeley Moynihan, the President, will preside. The price of tickets is 12*s.* 6*d.* (exclusive of wine). Individual members and members of coöperating organisations are particularly requested to make early application for any tickets they may require for themselves or guests to the Secretary, Federation of Medical and Allied Services, 12, Stratford-place, London, W. 1.

COURSE OF MEDICAL HYDROLOGY AT BATH.—As part of a course conducted last week under the auspices of the University of London, a practical demonstration of balneological and allied treatments was given at Bath. The visitors, who arrived on Thursday afternoon, were divided into small groups under the guidance of Dr. F. G. Thomson, Dr. Rupert Waterhouse, and Dr. R. G. Gordon, and attended demonstrations of the throat and nasal sprays and the inhalation of the radio-active gas, Scottish and alternating douches, the vapour bath, and the local Berthollet bath. From the Queen's Baths the party went on to the Royal Bathing Establishment, where they were shown the local whirlpool treatment, the aeration bath, the Plombières douche, the Vichy douche-massage, deep and reclining baths with the various forms of undercurrent douching, the Bourbon Lancy douche for reducing high blood pressure, and the Aix douche-massage. At the Cross Bath a demonstration was given of voluntary and controlled movements in the treatment of spastic and flaccid paralysis. On Friday morning, at the Royal Mineral Water Hospital, Dr. Gordon demonstrated on Osteoarthritis and Spondylitis, Dr. Waterhouse on Fibrositis, Dr. Vincent Coates on Infective Arthritis and Gout, and a visit was paid to the biochemical and bacteriological laboratory under the guidance of Dr. J. M. H. Munro. The afternoon was again spent at the Royal Baths, the groups being in the charge of Dr. Charles Curd, Dr. Preston King, and Dr. Clulow Nixon, when demonstrations were given of electrical treatments of various kinds, including electrical hot-air baths, both whole body and local treatments, the radiant heat and light bath, and ionisation to be used either alone or in conjunction with various forms of heat treatment. The four-cell bath was shown, the Bristow coil, the ultra-violet ray lamp, the Bergonié treatment used in cases of obesity and certain other complaints, the high-frequency current, diathermy and arc-lamp treatment. Apparatus for mechano-therapy was shown in the Zander Department. Before leaving the members were shown over the Roman thermæ by the Director of the Baths, Mr. John Hatton. The visitors were entertained to tea by the Mayor of Bath on the first day, and by the local members of the medical profession on the second day. A dinner party given by the Baths Committee afforded an opportunity for a discussion on bathing facilities and their application.

CHELSEA CLINICAL SOCIETY.—The annual meeting will take place at the Club Room, St. George's Hospital, on Tuesday, May 20th, at 8 P.M., when officers will be elected for the session 1924–25. A discussion on the Treatment of Non-venereal Genito-urinary Diseases will be opened by Sir John Thomson-Walker.

PROPOSED MEMORIAL TO THE LATE SIR WILLIAM MACEWEN.—It is proposed to commemorate in some suitable manner the late Sir William Macewen, and a preliminary meeting to discuss the proposal will be held in the Hall of the Royal Faculty of Physicians and Surgeons, St. Vincent-street, Glasgow, on May 22nd, at 4.30 P.M. All members of the medical profession are invited to attend this meeting. Communications may be sent to Andrew Freeland Fergus, 14, Newton-place, Glasgow, or to Arch. Young, 5, Park-gardens, Glasgow.

THE LATE DR. G. B. EADIE.—George Balfour Eadie, M.D. Glasg., who died suddenly on May 8th, was one of the anæsthetists to the Victoria Infirmary, Glasgow. After obtaining his M.D. (with commendation) in 1905, it was his intention to specialise in diseases of the throat and nose, but during the war, while on service, he sustained so severe an injury to his hands as to prevent him from pursuing this course. On his return from service he took up the administration of anæsthetics. His skill and care soon brought him private practice, and his untimely death removes a popular figure from the Glasgow Faculty.

NURSES' COÖPERATION.—This Coöperation, which was founded in 1891 to secure to nurses full remuneration for their work, has just issued its thirty-third annual report, which records a continuance of prosperity during the year 1923. All candidates for membership must be State registered, and no nurse is admitted to the staff unless she holds a three years' certificate from a recognised training school and has had some experience in private nursing. The gross receipts from patients amounted to £49,073, of which sum £46,204 were paid to the nurses. Investments standing in the name of the Coöperation amounted to £3244. During the year under consideration there was much illness among the nurses and consequently a large demand for benefit from the sickness and benefit fund. The address of the Coöperation is 22, Langham-street, Portland-place, London, W.

MANCHESTER AND SALFORD: POOR-LAW HOSPITALS.—Members of the board of guardians of the Manchester and Salford Poor-law hospitals are making strong protests with regard to Lord Knutsford's remarks in an address at a recent conference summoned by the Labour Party in London to discuss the "Hospital Problem." So far as these areas are concerned, they state, Lord Knutsford's allegations are entirely undeserved. In these hospitals—i.e., the Poor-law infirmaries—the patients receive treatment equal to that in the best public or private hospitals. Indeed, the Manchester Poor-law infirmaries deal with 1000 patients a month and in large industrial areas the Poor-law authorities spare no expense in maintaining these hospitals in the very highest state of efficiency. They have their own visiting surgeon, ophthalmologist, and other specialists as occasion requires. The old prejudice against Poor-law hospitals has gone. These hospitals are under the inspection of the Minister of Health. In Manchester many patients come to the hospitals of their own free will and pay for their treatment, and their number is steadily increasing. At a meeting of the Salford guardians held on May 9th the chairman said he felt it his duty to state that the Salford guardians had spared no pains in making Hope hospital a thoroughly efficient institution, where the patients could rely upon having at their disposal every requirement dictated by modern science. The true solution towards better organisation and coördination of the hospital systems lay not in State management and State control of the hospitals, but in a system of natural local development under the control of elected or selected individuals who were in close touch with local requirements. Poor-law hospitals were doing work of a standard that would bear comparison with the best that voluntary hospitals could show.

MATERNITY CENTRES: INFORMATION AS TO BIRTH CONTROL.—The Minister of Health recently received a deputation, introduced by Mr. F. A. Broad, M.P., on the subject of birth control. The deputation urged that the Minister should remove the embargo on the giving of information with regard to methods of birth control at maternity centres. In their opinion it was contrary to the whole policy of the Labour Party to deny working women access to knowledge which was readily available to people who could afford to pay for it. They also requested that the Minister should make it quite clear that doctors in the Public Health Service were free in their public capacity to give this information when they considered it medically advisable. The Minister, in reply, said that a clear distinction must be drawn between allowing access to knowledge and actually distributing knowledge. No one would seriously maintain that access to knowledge should be forbidden, but public opinion on this question was not so definite that it would allow State- and rate-aided institutions to do more than direct people in need of advice as to where it should be obtainable. The decision, in fact, must be with Parliament and not be assumed by administrative action. The speakers for the deputation included Mr. H. G. Wells, Mrs. Bertrand Russell, Dr. Frances Huxley, Mrs. Jenny Baker, and a statement was read from Dr. Sloan Chesser.

THE PEOPLE'S LEAGUE OF HEALTH.—The League is holding an International Health Conference at the British Empire Exhibition from May 21st to 24th inclusive. The subject of the Conference is the Latest Knowledge regarding the Causes, Treatment, and Prevention of Disease. Viscount Burnham will deliver the presidential address, and the Conference will be divided into seven sections, as follows: (1) Housing and House Sanitation, under the presidency of Mr. A. Neville Chamberlain, M.P.; (2) Food, under the presidency of Sir William Arbuthnot Lane, F.R.C.S.; (3) Air, Light, and Water under the presidency of Sir Henry Gauvain, M.R.C.S.; (4) Some Overseas and Other Diseases, under the presidency of Sir William Simpson, M.D.; (5) Mental Hygiene, under the presidency of Col. Sir Courtauld Thomson; (6) Industrial Hygiene, under the presidency of Prof. Sir Thomas Oliver, M.D.; (7) Legislation Desirable with Regard to Health Matters. On each day of the Conference the Tropical Health Exhibit in the British Government Pavilion will be demonstrated to the delegates. Further particulars may be had from the Hon. Organiser, 12, Stratford-place, W. 1, from whom nomination forms to the Conference may be obtained.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

THE ROYAL SOCIETY, Burlington House, W.
THURSDAY, May 22nd.—4.30 P.M., *Paper to be read:*—Prof. J. W. Gregory and C. J. Gregory: The Geology and Physical Geography of Chinese Tibet, and its Relations to the Mountain System of South-Eastern Asia. *Papers to be read in title only:*—Madge Kaye and Dorothy Jordan Lloyd: A Histological and Chemical Investigation of the Swelling of a Fibrous Tissue. (Communicated by Dr. R. H. Pickard.) C. H. Browning, Prof. J. B. Cohen, S. Ellingworth, and R. Gulbransen: The Antiseptic Action of Compounds of the Apocyanine, Carbocyanine, and Isocyanine Series. H. J. Watt: Dimensions of the Labyrinth Correlated. (Communicated by Prof. D. Noel Paton.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, May 20th.

GENERAL MEETING OF FELLOWS: at 5 P.M.
Ballot for election to the Fellowship.

Wednesday, May 21st.

HISTORY OF MEDICINE: at 5 P.M.
Annual General Meeting:
Election of Officers and Council.
Papers:
Dr. Haldin D. Davis: History of Diseases of the Skin.
Prof. Charles G. Cumston: Remarks on a Lay Medical Tract: "The Duke's Desk Newly Broken Up," by William Lovell, Gentleman and Traveller, London, 1660.

Friday, May 23rd.

STUDY OF DISEASE IN CHILDREN: at 5 P.M. (Cases at 4.30 P.M.)
Annual General Meeting:
Election of Officers and Council.
Cases:
Dr. Stanley Wyard: Child of 13 suffering from Myelogenous Leukæmia.
Other cases will be shown.
Presidential Address:
Mr. R. H. Anglin Whitelocke: Posture in the Treatment of Disease.

EPIDEMIOLOGY AND STATE MEDICINE: at 8 P.M.
Annual General Meeting:
Election of Officers and Council.
Paper:
Dr. Louis W. Sambon: The Elucidation of Cancer.

Saturday, May 24th, and Sunday, May 25th.

BALNEOLOGY AND CLIMATOLOGY.
Annual Provincial Meeting:
At Buxton.

LONDON DERMATOLOGICAL SOCIETY, St. John's Hospital, Leicester-square, W.C.
WEDNESDAY, May 21st.—4.30 P.M., Discussion on Tertiary Syphilis with Special Reference to its Cutaneous Manifestations, to be opened by Colonel L. W. Harrison, followed by Dr. Alfred Piney, Dr. C.H. Mills, and others. Clinical cases will be shown by the staff of St. John's Hospital. After the meeting the Fellows and Guests will dine together at the Criterion Restaurant.

MEDICO-LEGAL SOCIETY.—A meeting will be held at 11, Chandos-street, London, W. 1, on Tuesday, May 20th, at 8.30 P.M., when Sir Lenthal Cheatle will read a paper on Wounds of Entrance and Wounds of Exit. To be followed by a discussion.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, May 19th, to SATURDAY, May 24th.—CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL. Special Intensive Course (second week).—THE INFANTS HOSPITAL. Mon., Tues., Wed., Thurs., 2–3 P.M., Clinical Instruction in the O.-P. Dept. Mon., 3 P.M., Dr. Noel O. Richards: Dem., Nursery Hygiene and Clothing. 4 P.M., Dr. Donald Paterson: Anæmias of Infancy. Tues., 3 P.M., Dr. Amy Hodgson: Dem., Diet from 1–5 years. 4 P.M., Dr. Bertram Shires: Diagnosis by X Rays. Wed., 3 P.M., Dr. Eric Pritchard: Dem., Dried Milk. 4 P.M., Dr. Donald Paterson: Vomiting. Thurs., 3 P.M., Dr. Eric Pritchard: Dem., Patent Foods. 4 P.M., Mr. M. S. Mayou: The Prophylaxis of Certain Eye Diseases, including Myopia and Cataract. Fri., 4 P.M., Mr. Tyrrell Gray: Pyloric Stenosis.—LONDON LOCK HOSPITAL. Clinical work daily. Lectures at Dean-street as follows. Tues., 2.30 P.M., Mr. McDonagh: Clinical Demonstration with Exhibition of Paintings. Wed., 5 P.M., Mr. Lindsay Rea: Interstitial Keratitis, Congenital and Acquired. Thurs., 2.30 P.M., Mr. W. Victor Corbett: Interpretations of the Wassermann Reaction. 4.30 P.M., Mr. Lawrence Abel: Some Complications of Gonorrhœa in the Male. Fri., 4 P.M., Mr. Johnston Abraham: Gonorrhœal Rheumatism.—MAUDSLEY HOSPITAL. Mon., 3.30 and 5.30 P.M., Dr. Bernard Hart: The Psychoneuroses. Tues., 2.30 P.M., Dr. F. C. Shrubsall: The Practical Aspect of Mental Deficiency. 4.30 P.M., Sir Frederick Mott: Brain Syphilis, its Symptomatology and Treatment. Wed., 2.30 P.M., Dr. Mapother: Dem. in Clinical Psychiatry.—PRINCE OF WALES'S GENERAL HOSPITAL. Special Course in Intensive Medicine and Surgery (first week).—ST. MARK'S HOSPITAL FOR DISEASES OF THE RECTUM. Operations, Clinical Demonstrations, and Lectures will be in progress during the day (second week).

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, May 19th.—12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Simson: Diseases of Women. 4.15 P.M., Mr. Donald Armour: Lecture, Methods in the Diagnosis of Gall-stones.
TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients.
WEDNESDAY.—12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Pernet: Skin. Dept. 4.15 P.M., Dr. Owen: Lecture, Infantile Disorders in the First Ten Days of Life.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 12 noon, Dr. Scott Pinchin: Diseases of the Heart. 2 P.M., Mr. Bishop Harman: Eye Dept.
FRIDAY.—10 A.M., Dr. Drummond Robinson: Gynæcological Operations. 12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Dept.
SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
(At 4.30 P.M.)
MONDAY. May 19th.—Dr. W. Langdon Brown: Changing Standpoints in Metabolic Diseases.
TUESDAY.—Dr. F. G. Crookshank: Functional Hearts.
WEDNESDAY.—4 P.M., Mr. J. Howell Evans: Tumours of the Testicle.
THURSDAY.—Mr. J. Bright Banister: The Treatment of Contracted Pelvis.
FRIDAY.—Dr. L. R. Yealland: The Treatment of Neurosyphilis.

KING'S COLLEGE, Strand, W.C.
Monday, May 19th.—5.30 p.m., Prof. T. H. Brice, F.R.S.: The Development of the Human Embryo (University of London Advanced Lectures in Anatomy).
Tuesday.—5.30 p.m., Last Lecture.

ST. JOHN'S HOSPITAL, Leicester-square, W.C.
Tuesday, May 20th.—5 p.m., Dr. Wilfrid Fox: Nævi and Moles.
Thursday.—5 p.m., Dr. MacCormac: Rodent Ulcer.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
Thursday, May 22nd.—4 p.m., Mr. Higgins: Demonstration of Surgical Cases.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, W.
Tuesday, May 20th.—5.15 p.m., Prof. J. Barcroft: The Effects of Altitude on Man (Lecture IV.).
Friday.—9 p.m., Dr. Andrew Balfour: Historical Aspects of Malaria.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 p.m.)
Monday, May 19th.—(At the Hospital for Women.) Dr. Leith Murray: Leucorrhœa.
Tuesday.—(At the Maternity Hospital.) Mr. Leyland Robinson: Albuminuria of Pregnancy.
Wednesday.—(At the St. Paul's Eye Hospital.) Mr. Thos. Stevenson: Eye Cases.
Thursday.—(At the St. George's Hospital.) Dr. F. H. Barendt: Skin Cases.
Friday.—(At the Eye and Ear Infirmary.) Dr. Hugh E. Jones: The Extracranial Complications of Infective Middle-Ear Disease.

BRISTOL UNIVERSITY POST-GRADUATE DEMONSTRATIONS.
Wednesday, May 21st (at the Hereford General Hospital).—3.30 p.m., Mr. H. Chitty: Abdominal Surgery in Children.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.
Tuesday, May 20th.—4.15 p.m., Mr. J. Howson Ray: Varicose Veins.

Appointments.

Clausen, R. J., M.B., B.S. Lond., has been appointed Anæsthetist to the Metropolitan Hospital, Kingsland-road, N.E.
Ratner, E., M.B., Ch.B. Manch., D.P.H., Assistant Tuberculosis Officer, Manchester.
Stephenson, G. E., M.B., B.S. Durh., Medical Officer of Newcastle Prison.
Charing Cross Hospital: Banister, J. B., M.D. Camb., F.R.C.S. Edin., Assistant Obstetric Physician; Broster, L. R., F.R.C.S. Eng., Assistant Surgeon; Richards, W. A., M.B., B.S., Surgical Registrar; and Young, F. H., M.B., Ch.B. Camb., M.R.C.P. Lond., Medical Registrar.
Certifying Surgeons under the Factory and Workshop Acts: Yell, W. L., M.B., Ch.B. Aberd. (Wartle); Prentice, J. S., M.B., Ch.B. Glasg. (Shap, Westmorland).

Vacancies.

For further information refer to the advertisement columns.

Belfast Municipal Sanatorium, Whiteabbey.—Res. Med. Supt. £750.
Bolton Infirmary and Dispensary—Res. Surg. O. £250. Two H.S.'s. £150. Asst. H.S. £100.
Bristol, Clifton Dispensary, Dowry-square. Res. M.O. £300.
Cambridge, Addenbrooke's Hospital.—H.S. £130.
Cambridgeshire Tuberculosis Colony.—H.P. £100.
Carlisle, Cumberland Infirmary.—Jun. H.S. £150.
Chelsea Hospital for Women, Arthur-street, S.W.—H.S. £120.
East London Hospital for Children and Dispensary for Women, Shadwell, E.—Clin. Asst. for Throat and Ear Dept.
Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—P. for Mechano-Therapeutic Dept.
Exeter, Royal Devon and Exeter Hospital.—Hon. Anæsthetist and Hon. Asst. Anæsthetist.
Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—Radiologist. £100.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each £50.
Hospital for Women, Soho-square, W.—Res. M.O. £100.
Hull Royal Infirmary.—Cas. H.S. £130.
Kensington Tuberculosis Dispensary, 119, Ladbroke-grove, W.—Locum M.O. for one month. 35 guineas.
King Edward VII. Sanatorium, Midhurst, Sussex.—Med. Supt. £1000.
King's Lynn, West Norfolk and Lynn Hospital.—Res. Surg. O. £300.
Lancashire County Council.—Asst. County M.O. £800.
Leicester City Isolation Hospital and Sanatorium.—Asst. Res. M.O. £350.
Lichfield, County Mental Hospital, Burntwood.—Sen. Asst. M.O. £750.
Liverpool, Ministry of Pensions Hospital, Knotty Ash.—Consulting P. £300.
Liverpool, Royal Southern Hospital.—Hon. Gynæcologist and Hon. Asst. Orthop. S.
Manchester, Ancoats Hospital.—H.S. £100.
Manchester City.—M.O. £632 7s. 8d.
Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Sen. R.M.O. and Jun. R.M.O. £140 and £100 respectively.
National Hospital for the Paralysed and Epileptic, Queen-square, W.C.—Registrar. £200.
Newcastle-upon-Tyne, University of Durham College of Medicine.—Vacancy in Dept. of Bacteriology. £600.
Oldham County Borough Education Committee.—Asst. Schools M.O. £600.
Oxford, Radcliffe Infirmary and County Hospital.—H.S., Cas. H.S., and Res. Accoucheur. Each £120.
Preston, Lancs, County Mental Hospital, Whittingham.—Locum Tenens M.O. £8 8s. per week.
Queen Mary's Hospital for the East End, Stratford, E.—Hon. Asst. P.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.P. and H.S. Each £100.
St. Bartholomew's Hospital, E.C.—Radiologist. Asst. M.O. to X Ray Dept.
St. Mary's Hospital, W.—Surg. Reg. £200.
Sheffield, Jessop Hospital for Women.—Asst. H.S. for Gynæcological and Maternity Depts. £100.
Sheffield Royal Infirmary.—H.P. £60.
Stoke-on-Trent, Longton Cottage Hospital.—H.S. £150.
Wakefield, Clayton Hospital.—H.S. £200.
West End Hospital for Nervous Diseases, Welbeck-street, W.—Locum Tenens for post of Half-time Pathologist. £300.
West London Hospital, Hammersmith-road, W.—Med. Reg. £100.
Whitelands Training College, Chelsea, S.W.—M.O.
Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.
The Chief Inspector of Factories, Home Office, London, S.W., announces a vacant appointment at Shepton Mallet, Somerset.

Births, Marriages, and Deaths.

BIRTHS.

Druitt.—On May 7th, at North House, Petworth, Sussex, the wife of D. C. Druitt, M.R.C.S., L.R.C.P., of a son.
Eddison.—On May 7th, in London, the wife of Dr. H. Wilfred Eddison, of a son.

DEATHS.

Barker.—On May 9th, at Watford, suddenly, John Collier Barker, M.R.C.S., L.R.C.P., aged 62 years.
Batchelor.—On May 8th, in London, Charles Batchelor, M.R.C.S., L.R.C.P., of Fairfield-avenue, Staines, aged 61.
Cuffe.—On May 6th, at Johnstone-street, Bath, Edward Meade Cuffe, M.D., late Medical Officer at Wonford House, Exeter, only surviving son of the late Robert Cuffe, M.R.C.S., of Woodhall Spa.
Fraser.—On May 8th, James Alexander Fraser, M.R.C.S., L.R.C.P., of Western Lodge, Romford, Essex, in his 70th year.
Shattock.—On May 11th, at Wimbledon, Samuel George Shattock, F.R.S., F.R.C.S., aged 71 years.
Vicars.—On May 4th, at Guy's Hospital, London, Frederic George Vicars, M.D., aged 63 years.
Willes.—On May 7th, at Wellington-road, Bournemouth, William Willes, M.R.C.S., L.R.C.P., late of Greenwich, aged 69.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Royal Institute of Public Health: Congress in Bordeaux.—The Whitsuntide Congress, which meets at Bordeaux from June 4th–7th, will be divided as usual into a series of sections:—(1) State Medicine and Municipal Hygiene. Presidents: Sir Humphry Rolleston and Prof. C. Achard. (2) Naval, Military, and Air. Presidents: Vice-Admiral J. Chambers and Dr. Gérard, Ministre de la Marine. (3) Industrial Hygiene. Presidents: Sir Thomas Oliver and Prof. William Dubreilh. (4) Tropical Diseases. Presidents: Sir Ronald Ross and Prof. F. Mesnil, Institut Pasteur. (5) Pathology, Bacteriology, and Biochemistry. Presidents: Sir John Bland-Sutton and Prof. G. Mouriquand, Lyon. (6) Women and Public Health. Presidents: The Marchioness of Crewe and Mme. Wallerstein, Paris. These sections will meet concurrently on Thursday and Friday from 9 to 12 a.m. and 2 to 4.30 p.m., and on Saturday morning, the sectional presidential addresses being delivered at 9 a.m. on Thursday. The inaugural meeting of the Congress will be held at 2.30 p.m. on Wednesday in the Athénée Municipal, 53, rue des Trois Conils. Visits will be paid to the military exhibition arranged by the Ministry of War to the Port of Bordeaux and to other places of interest and beauty in the town and neighbourhood. The Congress dinner will be held on Friday evening in the Hôtel de Bordeaux. The London office of the Congress is 37, Russell-square, W.C. 1. The Bordeaux office is at the Faculty of Medicine, Place de la Victoire.

Notes, Comments, and Abstracts.

SOME SPAS OF SAVOY, THE DAUPHINY, AND THE JURA

The spa season in these districts of France runs from May or June to September, and during the last few years the numbers of British visitors who seek there health and refreshment has steadily increased. Apart from the intrinsic value of these resorts, together with other natural and social resources for various conditions of ill-health, much has been done to popularise them by the Office Français du Tourisme,[1] in connexion with which there are organised yearly visits of medical men both from this country and elsewhere to inspect and sample the fare provided at the different centres. In The Lancet of Feb. 9th, 1924, we referred to such a medical tour which took place last autumn, embracing the Jura, Savoy, and the Dauphiny It is with the spas visited on that tour, in which 180 medical men took part, that the present article deals. The party assembled in Lyons, and after a short stay at Aix-les-Bains, which is too well known to require a special description, the following places were visited.

Challes-les-Eaux.

This spa is only 20 km. from Aix, and occupies a pretty and picturesque situation in the broad Chambéry valley at the foot of Mont St. Michel. Challes is remarkable for the strength and activity of its sulphur waters and specialises in the treatment of nose and throat troubles. It is in great favour with public speakers and professional singers, and the cure is also recommended for "lymphatic" children and for chronic bronchitics. The climate is cool and bracing in May, June, and September, and there are charming walks and endless interesting motor runs in the neighbourhood. Fast trains do the journey from Paris in about ten hours, and there is comfortable and unpretentious hotel accommodation.

Uriage.

The next spa to be visited was Uriage, which occupies one of the most beautiful sites in the French Alps, being surrounded by wooded heights which protect it from winds and give it the calm and peaceful characteristics of Alpine climates. The beginning and end of the season—i.e., June and September—are recommended as the best time to visit the station, as the bathing establishment is less crowded and the hotel prices more moderate. There are two springs, (1) an iron spring which contains bicarbonate of calcium and the sulphates of calcium and magnesia, and (2) a sulphur spring which has a constant temperature of 73° F. at the source, and contains hydro-sulphuric acid and a small proportion of sodium monosulphide. The waters, especially the gases which they contain, are regarded as radio-active in a high degree. The bathing establishment is modern and well-equipped. The Uriage waters claim to be highly tonic in their character, and are strongly recommended for neurasthenic conditions. They are useful for scrofulous children and congenital syphilis, and glandular diseases are much benefited by their use. The internal and external exhibition of the Uriage waters is attended by marked results in various skin diseases such as eczema, impetigo, lichen, psoriasis, and acne, but it is probably the treatment of syphilis by the Aachen method of rubbing, combined with the use of the sulphur springs, which chiefly commends the spa to British physicians. The Uriage water seems to facilitate the absorption and to aid the action of the mercury. Attached to the Pump Room is an extensive park, with a tennis club and a golf links. There are numerous hotels, and many of them are first class.

Allevard-les-Bains.

Situated at an altitude of 1472 feet in a charming valley in the midst of the Dauphiny Alps, is Allevard-les-Bains. Notwithstanding its surroundings, the station is remarkably free from the mists which are so frequent on Alpine slopes. The characteristic of the water is the presence of sulphuretted hydrogen, and the great specialty of the spa is cold inhalations in the form of a fine spray. The water is also employed as vapour baths and local douches, and a feature of the establishment is aromatic baths made from decoctions of soothing or sedative plants. The clinical indication of Allevard is diseases of the nose and throat, and, indeed, the spa unites many advantages—an agreeable climate, beautiful scenery and excursions, and a liberal supply of water remarkably rich in H_2S.

Brides-les-Bains and Salins Moutiers.

From Allevard it is only a two hours' run to the twin resorts of Brides-les-Bains and Salins Moutiers in Savoy. These are two health resorts situated in the heart of the "Tarentaise," a part of Savoy comparable in many ways with the most beautiful parts of Switzerland. Salins is situated at an altitude of 1500 feet and a distance of one mile from Moutiers, and Brides at an altitude of 1800 feet two miles further on.

The waters of Brides and Salins each have their particular properties, but their combined employment often gives excellent therapeutic results. Brides is the French rival of Carlsbad and Marienbad, and its situation at the confluence of two mountain torrents tends to produce a tonic and bracing climate. The Brides water comes from a thermal spring at a temperature of 95° F., and its action is laxative, tonic, and diuretic. Its essential contents are sulphate of sodium, sulphate of magnesium, chloride of sodium, and sulphate of calcium. The principal indications for the Brides water are obesity and hepatic complaints and gastro-intestinal diseases, especially constipation with intestinal atony.

The cure at Brides is recommended for what the French love to call lymphatic children, and for convalescents from exhausting diseases, such as malaria. Local douches, maintained at a constant temperature by an automatic apparatus, are also used in the treatment of various gynæcological conditions, such as metritis and leucorrhœa.

Salins Moutiers is the French rival of Nauheim and Kissingen, and has been called the Thermal Sea of the Alps as its enormous yield of water (six million litres a day) permits its use as running water in both swimming and private baths. The temperature of the spring is 95° F., and its essential contents are chloride of sodium (12½ g. per litre), carbonate of iron, arsenate of sodium, carbonic acid, and what, for want of a more exact term, are described as radio-active substances.

These two charming resorts seem to be peculiarly adapted for Anglo-Indians, and the type of patient from tropical parts of our Empire who, before the war, used to flock to Carlsbad and Kissingen.

Fayet St. Gervais.

The spa is situated on slopes rising to an altitude of 1968 to 2788 feet on both banks of the river Bonnant, and Mont Blanc raises its snowy peak in the near distance. All the characters of a well-sheltered mountain climate are found. The town has an excellent water-supply of great purity, and all the amenities which an efficient municipal administration can provide. The springs and the bathing establishments are at Le Fayet, and there are three sources: (1) the Gontard; (2) the de Mey, both saline springs; and (3) the Guéridaud, a sulphur spring. The saline waters are at a temperature of about 104° F., and contain 5 g. of solids to the litre, the salts consist of sulphates of calcium soda and lithia, various bromides, silicate of sodium, and it is claimed that they are the most highly lithiated waters in Europe. The Guéridaud Spring also contains small quantities of hydrogen sulphide and of glairin. The St. Gervais waters are indicated in various arthritic troubles, more especially in those cases which are associated with hepatic, asthmatic, and cutaneous manifestations. The Guéridaud spring permits of its employment in the treatment of chronic skin diseases, where a most highly sulphurated water would be contra-indicated, and it is also, like other sulphur waters, used with benefit in various forms of rhino-pharyngitis. The climate of the spa is both soft and bracing, and a stay at St. Gervais often gives excellent results in neurasthenic conditions, and its bath appears to exercise a direct sedative action upon the glandular elements in delicate and nervous children who appear to thrive in this charming valley. Taken by the mouth the waters are diuretic, and mildly laxative and depurative.

St. Gervais is just 12 hours on the direct line from Paris, and the starting point of the Chamonix Martigny railway and of the funicular to Mont Blanc, so that apart from the local attractions of a fine park and numerous delightful walks, it is a splendid centre for excursions into the most interesting parts of the French and Swiss Alps.

Evian.

Evian is one of the principal towns of the Savoy, picturesquely situated on the slopes of the hills rising from the French shores of the Lake of Geneva. It nestles in a sort of amphitheatre which shelters it from high winds, and is kept cool in summer by the fresh breezes blowing from the mountains to the lake. The local *corps médical* consider that the spa owes much to its agreeable climate, which is tranquil without being relaxing, and produces very beneficial effects in various pathological conditions associated with nervous irritability or excitement. The springs of Evian are divided into several different groups, the principal one of which includes the celebrated Cachat Source, which is a cold, non-gaseous but highly agreeable water; it is only weakly mineralised, as it contains less than half a gramme of alkaline carbonates to the litre. The cure depends on the highly diuretic action of the water, which is taken in the morning fasting and between meals. The volume of urine passed after drinking the water often exceeds to a remarkable degree the amount of fluid ingested, and it is on this flushing of the intestinal and urinary passages that the treatment depends. All patients are advised to drink the water in the horizontal position, and to remain lying down for an hour or two afterwards to encourage diuresis. The Cachat water is delivered at the hotel in charming stone containers to enable clients to carry out the treatment with the minimum of discomfort. The clinical indications for a visit to Evian are numerous, but gout in its many manifestations, perhaps, stands at the head of the list. Next in importance are genito-urinary disorders where benefit may be expected from a careful régime, and diuresis promoted by a pure and efficient mineral water. Some forms of dyspepsia and colitis, especially when accompanied by diarrhœa, and a large range of hepatic conditions where the more drastic cure at Vichy is likely to be badly borne, do well at Evian. Neurasthenics and children and adolescents of neuro-arthritic parents who respond badly to home treatment are often " cured " by a course at Evian ; whilst the station specially caters for what the French politely term " plethoric gourmands," with whom supervision of the dietary and a thorough " washing out " by the waters yield excellent results in reducing weight and arterial tension. Evian is essentially a gay and fashionable spa and is resorted to annually by *le monde chic* of all Europe. It has fine hotels to which access from the lake side, where the casino is situated, is provided by a funicular service. Besides the magnificent Pump Rooms of the Cachat Source, there are a number of subsidiary establishments on the borders of the lake, and inland surrounded by the fine chestnut trees for which the district is famous, where the fashionable crowds can be readily avoided.

---

[1] Office Français du Tourisme: Services des Stations Thermales, 56, Haymarket, London, S.W. 1.

Divonne-les-Bains.

The Jura mountains are much less imposing than the Alps, but have a charm all their own. Divonne is situated on their eastern slopes, overlooking the plain and Lake of Geneva. Its altitude is 1685 feet, and it enjoys an equable and sunny mountain climate which enables it to keep open all the year round. The spa is in some ways unique, as its waters are neither warm nor mineralised ; *au contraire*, the springs maintain a temperature of 43° F. all the year round and contain no mineral salts. The bathing establishment is well organised, and hydrotherapy is associated with various other forms of treatment, including heliotherapy and psychotherapy. Divonne specialises in the treatment of various nervous conditions including genital weakness, and the peace and quiet of the surrounding country render it well adapted for rest cures. There is a good first-class hotel, and several others less pretentious, and its position makes it an excellent centre for excursions in the summer, while ski-ing and tobogganing are to be obtained during the winter on the neighbouring mountain slopes.

Salins-du-Jura.

Salins-du-Jura lies in a pretty valley, and is somewhat unique as its waters are only used externally. The springs are so rich in chlorides, and especially sodium chloride, that they are used commercially for the manufacture of common salt. The water is used both before and after the commercial process. After the extraction of the chloride of sodium, an oily, yellowish fluid is left which is styled the *Eaux Mères*, and is employed by itself for compresses and douches, or used to reinforce the spring water. The chief therapeutic indications for the Salins cure are various forms of surgical tuberculosis and some gynæcological conditions, such as metritis. There is no first-class hotel, but for visitors with modest tastes there is ample second and third-class accommodation.

Besançon.

The last spa to be visited was Besançon. La Mouillère is a sort of suburb separated from the town by the river Doubs and the Micaud road. The springs of Besançon, a fine town with numerous industries and a medical faculty of its own, are situated about three miles outside the town, and the water is piped into a centrally situated thermal establishment. The springs are saline in character, the chief constituent being common salt, but there are marked traces of bromides and iodides. Besançon specialises in children's diseases, and claims to be particularly suited for delicate children when there are contra-indications to sea air. The spa is also recommended for a long list of gynæcological conditions, including habitual abortion and sterility. There are two excellent establishments on the surrounding mountain slopes, where children who cannot be accompanied by their parents are treated. The children receive the cure at the baths and are given graduated exercises and a form of open air treatment under charming climatic conditions. Besançon offers all the amenities of life in a fine old French town, and there are numerous walks and endless excursions into the picturesque Jura.

TWO IMPORTANT HEALTH REPORTS.

(1) NORTH-WEST FRONTIER PROVINCE, INDIA.

The population of this Frontier Province in 1921 was found to be 2,135,573 ; the trans-border tribal tracts are not included in this figure, census enumeration not being practicable ; " the present agent, the chaukidar, is the best obtainable at the price, and a better cannot be substituted without an enormous increase in cost. Such a reform is outside practical politics at the present time." The birth-rate was 23·7, as compared with 28·6, the average for the five years, 1917–21 ; the actual decrease in numbers was greatest in Hazara district, where the births recorded were only 11,552, compared with 17,793, the average for 1917–21. Lieut.-Colonel William Anderson, I.M.S., Chief Medical Officer and Director of Public Health, who presents this report,[1] considers that the decrease in notified births in 1922 (10,349, as compared with the quinquennial average of 61,090) may be due to " the unfavourable effect of the actual scarcity which existed in 1921, and of the very general prevalence of malaria in that year that still continued." The birth ratios varied from 19·7 per 1000 in Hazara district to 29·9 in Dera Ismail Khan. The infantile mortality was 151·5 per 1000 births, a considerable improvement on the quinquennial average of 191·9 ; in the other provinces of India the ratio varied from 139·91 in Bihar and Orissa to 228·73 in the Central Provinces, the Frontier Province showing a lower ratio than any other except Bihar and Orissa.

Death-rates and Conservancy.

The general death-rate (21·7, as compared with 35·4, the mean ratio for the quinquennium 1917–21) showed a great improvement. This was chiefly due to the decline in influenza and malaria ; the ratio was lower than in any other province in India, Punjab coming next (22·07), and Central Provinces having the highest ratio (29·31). In the rural circles, embracing the greater portion (1,923,148) of the population, the mortality ratio was 21·26 per 1000, as compared with 35·57, the quinquennial average ; in the towns the respective ratios were 25·55 and 33·94 ; there was, therefore, a great improvement all round, but most marked in the dwellers in the country. Among the Indian non-military population (32,902) living in cantonments the mortality was only 8 per 1000 ; for the majority (17,003) living in Peshawar cantonment the ratio was only 1·58. A striking tribute to the efficiency of cantonment sanitation and standard of living is afforded by these figures. For Peshawar district as a whole the mortality was 18·8 ; for the rural circles 17·16, and for the city 33·67 per 1000 ; yet among the same (or a similar) class of population living in the cantonments the death-rate was only 2, or more exactly 1·58, per 1000. Lieut.-Colonel Anderson states that the high mortality in Peshawar city " is directly traceable to the very unsatisfactory conservancy arrangements which exist. Not only are the collection and transport arrangements defective, but the method of disposal results in the breeding of millions of flies in close proximity to the city walls. A great deal of the sickness which prevails is preventable, and as the Peshawar municipality has the necessary funds at its disposal its apathy in taking steps to improve its conservancy arrangements is lamentable. At Abbottabad, where the conservancy arrangements are the best in the province, the death-rate was least—namely, 11·01, less than one-third of that in Peshawar. The other three towns in Hazara district where sanitary arrangements are very defective [Nawanshar, Baffa, Haripur] have a higher death-rate [34·76, 25·78, 32·09 respectively] than any other towns in the province, excluding Peshawar. These facts speak for themselves."

Epidemic Disease.

The province was exceptionally free from epidemic disease during the year reported on. Cholera caused 92 deaths (0·04 per 1000, as compared with 0·81 per 1000 for the previous five years) ; of the total 129 cases 69, with 53 deaths, occurred in Peshawar city (giving a mortality ratio of 0·67 per 1000), and four deaths were reported in the adjoining Becketganj-Khawjaganj " notified area." The health officer considered that in all the Peshawar cases the exciting cause was unripe or over-ripe fruit ; experiments by Lieut.-Colonel F. P. Mackie, I.M.S., showed that cholera vibrios could be recovered from the interior of melons injected seven days previously, and from tomatoes and cucumbers injected three days previously. He emphasised the necessity for avoiding any damaged or bruised fruit during the prevalence of cholera. Anticholera inoculation was carried out, with a total of 1266 cases. Small-pox caused only 104 deaths, the quinquennial average having been 800 ; the mortality ratios were 0·05 and 0·37 respectively ; in the rural circles the ratio was 0·02, Hazara and Bannu being quite free ; in the towns the ratio was 0·34 and at Peshawar there were 54 deaths (0·68 per 1000); nothing is stated as to the condition of these cases, whether vaccinated or not. There was a definite decrease in fever mortality in all the "settled districts" throughout the province, the deaths registered from this cause numbering 39,984, as compared with the five-year average of 63,846; in Bannu district the ratio was only 14·22; in Hazara it was 23·25; for the whole province 18·72 per 1000. Relapsing fever had not been returned separately in previous years; in 1922 401 cases with 205 deaths were recorded in Peshawar, Kohat, and Dera Ismail Khan districts, the spirochæte being found microscopically in the blood; "as the great majority of the rural population are lice-infected, the extension of relapsing fever is easily explained. It is probably imported by Powindahs, who come across the borders in large numbers during the cold weather. They are invariably verminous and extremely insanitary in their habits." Plague prevailed in Peshawar city and to a slight extent in the district from May to July inclusive; the total cases during the year numbered 204, with 123 deaths (0·1 per 1000); in Peshawar city there were 188 cases and 115 deaths, the remainder occurring in the neighbouring villages. There was also one case (fatal) at Kohat. Out of 8404 rats examined 47 were found to be infected; 212 rat fleas captured in Peshawar and examined at the Kasauli Institute were all found to be *Xenopsylla cheopis*. "Since their appointment in 1913 the cost of maintenance of health officers has been met from provincial revenues. This year, owing to the need for retrenchment the local government decided that this expenditure should be borne by the local bodies for whom the health officers work." Peshawar and Dera Ismail Khan have agreed to this arrangement; "the other municipalities have agreed to pay a monthly allowance to a local assistant or subassistant surgeon in Government employ to do the work of a health officer in addition to his other duties." The responsibility for necessary public health investigation and action must nevertheless remain with the Provincial Government.

---

[1] Peshawar: N.W. Frontier Province Govt. Press, 1923.

A large and increasing amount of work has been done in the provincial bacteriological laboratory under Assistant-Surgeon H. D'Silva; 10,244 pathological specimens were examined during the year, and much interesting research carried out in connexion with autogenous vaccines, which were tried in 55 cases with marked success. Lieut.-Colonel Anderson concludes his report with the remark that "there might be much more progress if deputy commissioners would, to a greater extent, take a personal interest in the carrying out of measures recommended by the public health authorities." This is quite true, and happily it is frequently, if not generally, the case that these officers do take such an interest; if this is not so the public health is likely to suffer, and the responsibility for this would undoubtedly lie, in a greater or less degree, with the executive authority.

Hospitals and Dispensaries.[2]

The report on Hospitals and Dispensaries in the North-West Frontier Province for 1922 deals with the working of 80 medical institutions. Owing to the need for financial retrenchment seven dispensaries had to be closed, while three new dispensaries were opened for the South Waziristan and Tochi Scouts. These institutions are divided into three groups, in the first of which, comprising what are known as "State Public, Local Fund, and Private-aided" hospitals and dispensaries, 47 in number, a total of 12,792 in-patients and 798,479 out-patients were treated, as compared with 11,434 and 719,537, the averages of the preceding quinquennium. The daily average of in-patients was 486 and of out-patients 3509, as compared with 421 and 3367 for the quinquennium. The year was exceptionally healthy in this province, the mortality among the general population being only 21·7, compared with 35·4 per 1000, the quinquennial average. Malaria was much less prevalent than usual. "It has been found that an increase of malaria occurs about a fortnight after the minimum wet bulb thermometer reaches 18° to 22° C. It is only between these temperatures that the malarial parasite exists in the circulation in a form that is undergoing further development in the mosquito and so being spread." In Peshawar such a temperature range prevails from the last week in April to the first week in June, and from the second week in September to the first week in October. Malaria in this province occurs especially in May and June and in the autumn. Cinchona febrifuge, costing less than a third of the price of quinine, has been found by Major H. W. Acton, I.M.S., and other observers to give a higher percentage of cures than quinine, and has been largely used with very good results. Only two cases of cholera were admitted to hospital, and ten treated at their homes. A small outbreak of plague occurred in Peshawar district, 14 cases being treated at their homes; no death is recorded.

In the second group, "State Special" hospitals, including those for police, frontier constabulary, militia and scouts, canals and railways, numbering 28, there were 162,766 patients under treatment, a large increase on the quinquennial average of 118,803; this was due to the opening of three railway construction hospitals in the Khyber in 1921, and to the great increase in the strength of the Tochi and South Waziristan Scouts. The third group, "Private non-aided" institutions, consists of the Mission Hospitals at Peshawar, Dera Ismail Khan, and Karak, the Zenana Mission at Mardan, and the Victoria Diamond Jubilee Hospital at Peshawar; in all 43,027 patients were treated, indoor and outdoor. The term "dispensary" is used for what would be correctly be called "hospital," as in-patients are included in the numbers stated. Lieut.-Colonel Anderson, in reviewing the year's work, notes that on the whole the year was exceptionally healthy, and regrets that need for retrenchment necessitated a reduction of four in the number of dispensaries maintained, and of 14 in the cadre of sub-assistant surgeons. Nevertheless the hospital attendances were more than 116,000 in excess of the quinquennial average and the operations performed increased by nearly 5000, this being "a reliable criterion of the popularity and utility of a hospital."

Jails.

In the jails and judicial "lock-ups" of the Frontier Province the total prisoners of all classes confined in 1922 numbered 13,494, as compared with 12,271, the quinquennial average for 1917–21; and the daily average prison population was 3424, against 2929 in the preceding year. Serious overcrowding existed in all jails and lock-ups, on account of transfer to the Andaman Islands being stopped, and the number sent to other provinces greatly reduced. Owing to this large numbers of prisoners sentenced to labour could not be employed for lack of factory accommodation, as many as 400 such being idle in Peshawar jail at one time; nevertheless the cash profits amounted to Rs.52,649, and the earnings per head of those employed in the manufactories to Rs.121.9.0, as compared with Rs.24,597 and Rs.56.6.0, the quinquennial averages for 1917–21. "The object of the jail department is to obtain a regular market for the articles it manufactures. . . . Larger and regular orders from public consuming departments are required." The overcrowding occurred only among male prisoners, their daily average numbering 3257, while the total accommodation was for 2509 only; the excess number were kept at night in tents and worksheds. The total admissions to hospital numbered 4351, giving a ratio of 1370 per 1000 of average strength; for the quinquennium, 1917–21, the figure 2172 is stated both as the number and as the ratio per 1000 of hospital admissions—an obvious error, for the correction of which figures are not available in the report. The average constantly sick rate for 1922 was 40, and mortality 26·45 per 1000; "on the whole, the health of the prisoners was good. Of the 72 prisoners who died, 51 had been in prison for less than one year." (Page 13.) On the same page, however, and in Statement No. XIV., p. xxxvii., the total deaths are stated as 84 (including one female); the number 72 refers to male convicts only. Malaria was prevalent in Peshawar jail, but of a mild type. Of 1626 admissions to hospital only two cases proved fatal, and these were complicated with cirrhosis of the liver and dysentery respectively. Out of 1450 prisoners examined in this jail 107 had enlarged spleen. Dysentery, so frequently a jail scourge, caused only 32 admissions and 2·22 deaths per 1000 average strength among the convicts; at Abbottabad these ratios were 74 and 12·34 respectively. Not a single case of cholera occurred in any jail throughout the year. Lastly, of the 2960 convicts discharged during the year 44·8 per cent. had gained, and 26·5 per cent. lost in weight, a satisfactory testimony to the general health arrangements of the jails, though not equal to the quinquennial average results (1917–21), which showed a gain in 51·5 and a loss in 23·3 per cent. Lieut.-Colonel Anderson concludes his report[3] by emphasising the urgent need for a central jail, and an increase in the staff of warders; chronic overcrowding and lack of factory accommodation are also conditions needing immediate attention.

* * *

(2) PUBLIC HEALTH IN TANGANYIKA.

THIS territory consists of that portion of the former colony of German East Africa which, under the Treaty of Peace, the principal Allied and Associated Powers agreed should be administered under a mandate by His Britannic Majesty. The territory extends from the Umba River on the north, to the Rovuma River on the south, the coast line being about 500 miles in length, and includes the adjacent islands; the total area is about 365,000 square miles. The seat of government is Dar-es-Salaam (population approximately 25,000). Portions of the great lakes of Central Africa are included in the territory—viz., the southern portion of Lake Victoria, the eastern shores of Lake Tanganyika, and the northern and north-eastern shores of Lake Nyasa ; there are four smaller lakes and numerous rivers. The highest points in the territory are in the north-east, where are the extinct volcanoes, Kilimanjaro, which rises to 19,720 feet, and is snow-capped, and Mount Meru (14,960 feet) ; in the south-west are the Livingstone mountains, where the highest peak is over 9000 feet. The system of administration is to support and supervise, with the least possible interference, the native authority as existing or established. The population, as shown by the census taken in 1921, was : Europeans, 2447, of whom 1598 were British subjects ; Asiatics, 14,991 ; and natives, 4,107,000. No statistics relating to native births and deaths are available. The population of the up-country districts is almost certainly increasing, but the birth-rate on the coast is low. The sterility of the Swahili women is due to immorality, and, to some extent, probably, in-breeding.

[3] Administration Report on Jails, N.W. Frontier Province, 1922, Peshawar Government Press, 1923.

Superstitions and Habits.

The official report for 1922 records that an Ordinance making witchcraft a punishable offence has been passed to check the activities of the medicine men. To the influence of these may be attributed the barbarous practice of infanticide, which prevails among the Wapare in Moshi district. Children born with some abnormality or considered by the diviners to be unlucky for a great diversity of reasons, such as the cutting of the lower before the upper teeth, or the offspring of parents who have failed to undergo initiation into certain tribal ceremonies, are done to death by deliberate starvation and neglect, suffocation, poisoning, or injury at birth, or, if a less obvious method is required, by exposure to the unhealthy climate of the low country. In general, the parents would not of their own accord abandon such children, and in many cases have preferred to give them away to strangers, but they are more or less compelled by popular opinion, or by the fear of incurring blame for any general misfortune that may befall the community, such as a drought or epidemic. Fermented liquor is manufactured by natives from various materials, such as the cocoanut palm, honey, grain, &c., and its consumption at most native ceremonies is demanded by tribal custom. While its sale in townships can be controlled, prohibition or restriction in the villages is well-nigh impossible. Taken in moderation, native beer is a harmless concoction, and is part of the daily food ration of the old men, but over-indulgence in it leads to quarrels, and is responsible for the majority of crimes of violence. The chiefs are empowered to prevent the supply of liquor to young persons, and to restrict drinking bouts. Natives in the Mwanza district were discovered distilling a potent form of spirit from bananas on Ukerewe Island, whence it was carried by canoe to the mainland and thence retailed ; the culprits were brought to justice. A cottage hospital was opened at Moshi, and a European ward added to the Mwanza hospital, nursing sisters being posted to each of these districts. A block of the Tanga hospital was converted for the reception of Asiatics, and the accommodation at the native hospitals at Dar-es-Salaam and Iringa was enlarged. During the year 12,400 native in-patients and 97,700 out-patients were treated in Government hospitals, at which a medical officer or sub-assistant surgeon was stationed. In many of the sub-districts, where no regular medical establishment exists, minor ailments were attended to by Indian compounders or native dressers. Appreciation by the native of the value of medical aid increases, but the innate conservatism of the unsophisticated often keeps them from presenting themselves for treatment until their own medicines have failed, and the disease has made headway. Praises must be given to the missions, which perform a great deal of excellent work, and in many cases include qualified doctors or nurses among their staffs.

Infectious Disease, Endemic and Epidemic.

Of infectious diseases plague, small-pox, and cerebrospinal fever are endemic in the territory. In the Singida sub-district of Dodoma, where plague has certainly existed since 1918, there were 23 deaths from the disease, as against 149 in 1921. Following the return of a native from that area to his home, a disease which was almost certainly plague was reported at Shinyanga in the Tabora district ; 13 deaths occurred, but prompt measures were taken, and no recrudescence has been recorded ; 46 deaths from small-pox were notified from various districts. Vaccinations steadily proceed, and 178,750 doses of lymph were prepared in the laboratory and distributed. An outbreak of sleeping sickness in the Mwanza district caused grave anxiety during the year. This epidemic has been proved to be due to infection with *Trypanosoma rhodesiense*, the vector being a tsetse of the morsitans group. This occurrence of the Rhodesian form of sleeping sickness many hundreds of miles north of any previous recorded outbreak is ominous, as very large areas of the territory and neighbouring countries are infested with *Glossina morsitans*, and a generalised infection of tsetse throughout these areas would be disastrous. Fortunately this epidemic occurred in an isolated flybelt, and the energetic measures instituted since the disease was discovered appear to have been successful in controlling the outbreak. The natives have been removed to fly-free areas, and the patients and suspected cases segregated in isolation camps, where 41 remained at the end of the year. There is no doubt that the disease had been present in the area for three or four years, and was responsible for several hundred deaths which the natives had attributed to some form of elephantiasis. Venereal disease is very common in the larger towns, and reports indicate that the Mwanza and Bukoba districts are heavily infected. Syphilis is responsible for a large percentage of the heavy infantile mortality, and to an even greater extent for reduction in the birth-rate. The more progressive chiefs are aware of the dangers, and, in some districts, are encouraging infected persons to go into hospital, while the tribal courts in Dodoma have started to impose a fine of ten head of cattle on any man found proved to have communicated the disease. Most districts are malarious, and the spirillum tick is widespread in certain areas.

A Variety of Climates.

The climate varies greatly, according to the height above sea-level. Roughly, four climatic zones can be distinguished (though even among these there are considerable local variations), viz. : (1) The warm and rather damp coast region, with its adjoining hinterland ; here conditions are tropical, though not unpleasant except just before and during the rainy seasons when the heat is trying and the atmosphere humid ; the average yearly temperature is 78° F. (2) The hot and moderately dry zone between the coast and the central plateau ; this is characterised by low humidity of atmosphere, less rain, and a temperature rather lower, but with greater daily and yearly variations. (3) The hot and dry zone of the central plateaus between 2000 feet and 4000 feet in height ; the prevailing characteristics are low humidity, little rainfall, and a fairly high mean temperature ; the heat is dry, but not so trying to the European as the moist and steamy warmth of the coast, while the nights are invariably cool. (4) The semi-temperate regions around the slopes of Kilimanjaro and Meru, of the Usambara highlands, the Ufipa plateau, and the mountainous areas of the south-west (5000 feet to 10,000 feet) ; frosts occur at the higher altitudes, and the nights are cold ; these districts enjoy a bracing climate, and alone can be considered healthy for Europeans, but prolonged residence in these altitudes is apt to produce nervous strain, even though physical fitness is maintained. There are two well-defined rainy seasons annually. Generally speaking, the long rains begin in February or March, and last for two or three months, while the short rainy season is in October to November, but the rainfall is low for a tropical country, and droughts are not infrequent.

THE PUBLIC SCHOOLS YEAR BOOK.[1]

THE Public Schools Year Book for 1924 is the thirty-fifth of the annual series. It is described as a comprehensive guide to public and preparatory schools, universities, professions, all public services throughout the Empire, and business careers, and indeed bears out the claims made for it. It is to the short article on the medical profession that we naturally turn ; the object of this article is to outline to the intending student what steps he should take to ascertain the different methods of entering our profession, and also to give him some idea of the various careers that are open to him, after he has obtained his qualifications. The information given appears to be accurate and the advice sound as far as it goes ; for further details the prospective student is referred to the Students' Number of THE LANCET. The medical scholarships obtainable at various institutions are set out clearly in tabular form. Parents who wish to choose schools, universities, or professions for their sons cannot do better than consult this manual.

Observations

ON A

COUNTY VENEREAL DISEASES SCHEME:

THE DEFECTS IN ADMINISTRATION.

A Communication to the Imperial Social Hygiene Congress (V.D. Treatment Section) on May 14th, 1924,

BY J. J. BUTTERWORTH, M.D. MANCH., D.P.H.,
MEDICAL OFFICER OF HEALTH, LANCASHIRE COUNTY COUNCIL.

THE county of Lancashire presents every kind of problem from the administrative point of view with regard to venereal diseases. The north is almost entirely rural, devoted to dairy farming and grazing, thinly populated, and broken up in its northernmost part by hills and mountains into remote valleys to which access is difficult. In the west are the flat and level areas of the rich agricultural lands of the Fylde and West Lancashire. In the east, south, and south-west are the densely populated areas of industrial Lancashire.

The extreme length of the county measured in a straight line on a map is 76 miles, and its extreme breadth is 45 miles, but by existing means of transport its actual length is about 120 miles and its breadth about 60 miles. The following are the gross figures:—

Geographical County.

	Area.	Population.
Geographical county	1,194,555	4,927,484
17 county boroughs	140,047	3,181,693
Administrative county—i.e., are under administration of county council for venereal diseases purposes—		
19 municipal boroughs	86,426	580,924
83 urban districts	255,458	922,749
19 rural districts	712,624	242,218
Total administrative county	1,054,508	1,745,891

Rateable value, £11,228,326. 1*d.* in the £ produces about £43,500.

The predominantly industrial character of the county is shown by the following figures:—

Occupations of Persons (Geographical County).

(Census, 1921.)

	Males.	Females.
Total population	2,332,931	2,594,553
Number of persons not engaged in occupations	189,522	1,233,336
Number of persons 12 years of age and upwards engaged in occupations	1,614,243	833,717
Approximate number of persons occupied—		
Metal workers	218,000	8,000
Transport	213,000	9,000
Textile workers	183,000	317,000
Commercial occupations	140,000	72,000
Clothing and textile goods	33,000	79,000
Mining and quarrying	110,000	2,000
Building and allied trades	77,000	—
Clerks and draughtsmen	81,000	50,000
Wood, furniture, &c.	64,000	4,000
Warehousemen, storekeepers, &c.	48,000	24,000
Professional occupations	31,000	38,000
Agricultural	48,000	5,000
Public administration and defence	31,000	6,000
Food, drinks, &c.	22,000	20,000
Paper, books, &c.	21,000	16,000

Cotton Trade.—Over 1000 spinning mills employing 200,000 persons; 250,000 persons engaged in weaving and finishing cotton goods. Total population engaged in textile work, 500,000.

Coal Mining.—Twenty-five million tons mined annually in Lancashire. Estimated amount of coal still available in the county, 4,000,000,000 tons.

Stone and Ore Mining.—Stone or rock or metallic ores mined annually in the county, 3,750,000 tons. Persons engaged in mines and quarries, 112,000.

Agriculture.—Total area of county, 1,200,000 (approx.) statute acres. Area cultivated, 800,000 acres. Persons employed in agriculture, 53,000. Area of Lancashire farms, average 36·5 acres.

SYNOPSIS OF COUNTY SCHEME.

(A) *Treatment Centres.*

Arrangements for the treatment of venereal diseases have been made by the county council with 22 hospitals and three ad hoc clinics in the geographical county. These treatment centres, with one exception, are situated in the county boroughs and are not evenly distributed geographically, being mainly in the thickly populated areas of south-east Lancashire. The residents in many of the rural and smaller urban districts have to travel considerable distances for treatment. There are several other hospitals in the administrative county which might be used for the treatment of venereal disease, but it has not been possible, for various reasons, to make suitable arrangements.

Table I. is a synopsis of the work carried out in the treatment of residents in the administrative county at the centres since the beginning of the scheme in 1918:—

TABLE I.—*Number of Persons Resident in the Administrative County* who have Attended the Treatment Centres.*

Year.	No. of residents in the administrative county area attending treatment centres for the *first* time and found to be suffering from—					Total No. of attendances of county residents at out-patient clinic.	Aggregate No. of in-patient days.
	Syphilis.	Soft chancre.	Gonorrhœa.	Conditions other than venereal.	Total.		
1918	674	12	173	104	963	9,010	950
1919	1510	94	729	408	2741	22,732	2838
1920	1433	85	802	496	2816	31,096	2490
1921	1104	33	622	414	2173	32,739	2367
1922	701	17	573	399	1690	29,420	1490

* It might be well to repeat that the term "administrative county" means the whole of the geographical county, excluding the 17 county boroughs.

It will be observed that the number of patients is tending to decrease, and the average number of attendances to increase. It has been found by experience that very few children or babies are presented at these clinics.

Period of Attendance at the V.D. Clinics.—From the returns made to the County Public Health Department from certain of the venereal diseases treatment centres in Lancashire during the six years 1918–23 statistical details have been collated. It has not been found possible from the information available to include in them the large treatment centres in Liverpool and Manchester; and from certain other institutions the returns do not cover the whole period of six years. In most instances the agreements with the treatment centres are between the management of the institution and the county borough council, and the county council has to rely for statistical details on returns, often incomplete, supplied by the county borough health departments.

I have endeavoured to ascertain, from the data available, the proportion of the total persons attending clinics who *complete* the full course of treatment, or who cease to attend *before* completion of the course. The statistics here quoted refer to 23,270 persons—males 17,164, and females 6106—who attended certain Lancashire treatment centres, for which complete returns have been received, between the date of the commencement of the county scheme (1918) and Dec. 31st last year.

The following tabular statement shows, as far as the data available permit, the gross percentage of persons who actually completed the course and attended the final tests, contrasted with those who ceased to attend at various stages of treatment.

TABLE II.—(Years 1918–23.)

—	Syphilis.		Soft chancre.		Gonorrhœa.	
	M.	F.	M.	F.	M.	F.
	%	%	%	%	%	%
Persons who ceased to attend the clinic at various stages of treatment and before the *final* tests as to cure	79·3*	80·5*	57·5*	71·9*	60·7*	61·0*
Persons transferred to other treatment centres after treatment	6·4	4·7	3·6	2·2	8·9	10·4
Persons discharged from the clinic after completion of treatment and observation ..	14·2	14·7	38·8	25·8	30·3	28·5

TABLE III.—*Yearly Percentages :—*

(A) Year 1918.

Persons who ceased to attend the clinic at various stages of treatment and before the *final* tests as to cure	80·3*	78·6*	90·9*	—	68·0*	66·6*
Persons transferred to other treatment centres after treatment	—	—	—	—	—	—
Persons discharged from the clinic after completion of treatment and observation ..	19·3	21·3	9·1	—	32·0	33·3

(B) Years 1919 and 1920.

Persons ceasing to attend clinic before completing a course of treatment	45·7	46·3	23·4	41·3	45·0	52·1
Persons ceasing to attend after completion of a course of treatment, but before *final* tests as to cure	36·6	38·1	36·8	35·6	21·7	23·7
Persons transferred to other treatment centres after treatment	5·4	2·7	2·5	—	6·1	4·8
Persons discharged from the clinic after completion of treatment and observation ..	12·1	12·7	37·2	23·0	27·0	19·4

(C) Years 1921, 1922, and 1923.

Persons ceasing to attend the clinic before completing the first course of treatment ..	24·4	24·5	25·6	40·0	33·2	32·1
Persons ceasing to attend after one or more courses but before completion of treatment	30·1	30·5	—	—	1·8	1·4
Persons ceasing to attend after completion of treatment, but before *final* tests as to cure	22·4	22·5	25·1	20·0	21·2	19·7
Persons transferred to other treatment centres after treatment	7·8	6·7	6·4	20·0	10·7	13·3
Persons discharged from the clinic after completion of treatment and observation ..	15·2	15·5	42·7	20·0	32·9	33·3

* Includes a large percentage (in the case of syphilis 35 to 40 per cent.) who completed the course of treatment, but did not attend for the final tests.

Conclusions from the Tables.—As regards syphilis, approximately 50 per cent. of both sexes cease to attend at the treatment centre *before* completing the full course of treatment. During the last three years (1921–23), as compared with 1919 and 1920, there was an increase in the percentage of persons discharged from the clinics *after* completion of treatment and observation, the percentage of the sexes being equal. In gonorrhœa cases the percentage of completed attendances is higher than in syphilis.

(B) *Arrangements for General Practitioners.*

The Lancashire County Council have made arrangements by which medical practitioners practising in the administrative county area can be supplied gratuitously with the necessary outfits for collecting materials for examination from persons suspected to be suffering from venereal disease, and scientific reports upon the materials submitted are furnished to them direct by the pathologist.

The laboratories available for such examinations are :—

Liverpool : The University of Liverpool, City Laboratory and School of Hygiene, Mount Pleasant. (Prof. Beattie.)

Manchester : The University of Manchester, Public Health Laboratory, York-place, Oxford-road, Manchester. (Prof. Topley, Director.)

Burnley : The Borough Health Department Laboratory.

In addition to these laboratories, several of the hospitals carry out portions of the bacteriological work. It is not possible to state the number of patients treated by general practitioners either privately with their own drugs or with arsenobenzol compounds supplied by the county council. It would be interesting to receive from practitioners an annual return of the number of persons treated by them.

Free Supply of Arsenobenzol Compounds.—The county council supply free of charge arsenobenzol compounds to approved medical practitioners, and Table IV. shows the amount of work carried out.

TABLE IV.—*Number of Outfits and Number of Doses of Arsenobenzol Compounds Issued by County Council to Medical Practitioners.*

Year.	No. of outfits issued by county council to medical practitioners.				Result of exam. of specimens forwarded to Manchester laboratories.		Supply of arsenobenzol compounds.	
	Wass. test.	Detection of spirochæte.	Detection of gonococci.	Total.	Positive. Per cent.	Negative. Per cent.	Total No. of practitioners "approved."	Total No. of doses supplied.
1918* ..	195	10	51	256	40·14	59·86	27	269

1923 ..	900	5	61	966	38·97	61·03	123	845

* Portion.

The addresses of the "approved" practitioners show that they are grouped for the most part around the large towns in the vicinity of the venereal disease treatment centres. The greater number of the "approved" practitioners received their training during military service. Practitioners who did not receive training in venereal disease work during the war have not, as a rule, taken up this work, as it is difficult under present conditions to spare the necessary time and money for post-graduate work. Some of these continue to treat syphilis with mercury only. In the course of my work I meet a large number of general practitioners, and those in practice in rural areas and in the smaller urban districts state that they rarely see cases of obvious venereal disease.

EDUCATIONAL WORK.

The County Public Health Department began educational work to combat venereal disease in the year 1917 by the appointment of two organisers—one male and one female—and since 1920 has continued the work mainly by the services of a lady organiser and a panel of about a dozen medical lecturers. The propaganda and educational arrangements have comprised lantern and film lectures in theatres, picture-houses, public halls, &c., talks to mothers in child-welfare centres, and lectures to men and women in clubs, works, institutes, &c. Special courses of lectures in biology have been given by a medical woman to teachers.

Table V. sets out the amount of work carried out in these directions.

TABLE V.—*Approximate Audiences Reached by Propaganda Work Carried Out by the County Council Public Health Department.*

Year.	Lectures and addresses by organising lecturers, &c.			Medical lectures.			Lectures to—		Lantern lectures.	Film lectures.	Works meetings.		Total.

M.=Men. W.=Women. Mx.=Mixed.

I think it can be argued that the campaign inaugurated against venereal diseases during the last few years has already gained a great measure of success in certain directions. In my own county a considerable section of the population, by means of propaganda, has been made to realise the contagiousness and serious results of venereal disease. Table V. shows that we have brought the subject before more than a quarter of a million people during the last five years. The attitude that even the innocent sufferer should be treated as a social outcast has been broken down. Many of the infected persons, by treatment, have been rendered non-infective. The governing bodies of hospitals are beginning to realise that these diseases can no longer be neglected and that treatment must be provided. The best results have been achieved in the treatment of syphilis, particularly in the male.

The facilities in this county for treatment of infected persons are, with more or less difficulty, within the reach of all. The county council has issued, free of charge, over 800 railway vouchers to enable persons to travel from their homes to treatment centres. The campaign against the disease, however, requires development in certain directions.

The greatest defects in a number of the present schemes are (*a*) the lack of proper provision for the treatment of infected children, (*b*) the lack of proper provision for the discovery and treatment of gonorrhœa in the female, and (*c*) the difficulty of providing treatment with sufficient privacy for the respectable woman who objects to have to wait her turn in company which is often very mixed and undesirable. It is mainly with the first two defects that I propose to deal here, as, in a large number of cases the sufferers are innocent victims and therefore most worthy of treatment and consideration.

EXTENT OF THE PROBLEM.

Before discussing any administrative action it is necessary to know something of the extent of the problem.

(A) *Children Suffering from Venereal Diseases.*

These children can be divided into two classes: (1) Children of school age, (2) children under school age.

(1) *Children of School Age.*—About two years ago I instructed the medical men on my staff working in the Lancashire county schools and child welfare centres to carry out an investigation into the incidence of the signs of congenital syphilis in children attending the elementary schools. It was impracticable to use the Wassermann test in the investigation. As the result of the clinical examination of several thousands of children, I formed the following conclusions:—(*a*) That the gross manifestations of congenital syphilis in school-children resident in the rural districts of the county are very rarely seen; (*b*) that the gross manifestations of congenital syphilis are occasionally seen in the routine examination of school-children in the smaller towns (less than 0·15 per cent.); (*c*) there was some evidence that congenital syphilis, which had remained latent, was lighted up by intercurrent disease—thus, one child developed signs of congenital syphilis after measles, and another after the removal of tonsils and adenoids; and (*d*) there were certain cases, but few in number, in which the medical officers thought a Wassermann test necessary before a definite opinion could be expressed.

(2) *Children under School Age.*—The medical officers working in the county child welfare centres are unanimous in stating that they see and suspect the existence of syphilis more frequently in the babies attending the centre than in school-children, but that it is by no means a common disease in these children. They think, however, from the evidence supplied by their health visitors that the disease has its greatest incidence in the premature and ailing infants who die in the first months of life or remain too feeble and ill to attend the centres. In other words, the infected children die off and do not survive till school age. Several of the medical officers express the opinion that syphilis is frequently a cause of stillbirths.

Table VI. shows the number of stillbirths, &c., reported by midwives practising in the administrative county area:—

TABLE VI.

Year.	Total births in county area.	No. of births attended by certified midwives practising in county area.	No. of stillbirths reported by certified midwives.	Percentage stillbirths reported by midwives to total births attended by them.
1914	38,507	21,880	498	2·27
1915	34,595	20,941	392	1·87
1916	32,695	17,069	397	2·32
1917	28,420	15,592	361	2·31
1918	27,736	14,966	305	2·03
1919	28,799	16,240	381	2·34
1920	39,767	21,843	479	2·19
1921	36,558	19,566	443	2·26
1922	32,011	17,046	401	2·35
1923	30,672	15,763	359	2·27

There is a strict supervision of the work of certified midwives practising in the administrative county area, and the record of stillbirths stated above may be taken as approximately correct. "Stillbirths" include all infants born dead after the twenty-eighth week of pregnancy. Table VI. shows that in spite of the great reduction which has taken place in the postnatal causes of infant mortality during recent years, the causes of antenatal death remain as potent as ever.

[Here Dr. Butterworth referred to the work of Dr. J. N. Cruickshank on "Maternal Syphilis as a Cause of Death of the Fœtus and of the New-born Child," recently published by the Medical Research Council (vide THE LANCET, March 22nd, p. 608 et seq.)]

(B) *The Discovery of Gonorrhœa in the Female.*

In the rural and small urban districts of under 20,000 population in a large county like Lancashire the discovery and treatment of gonorrhœa in the female is a very difficult administrative problem. One of the greatest difficulties is our lack of knowledge of the incidence of the disease. The sources of information are meagre. I obtain a certain amount of information as to the occurrence of gonorrhœa in women through the administration of the Midwives Acts.

Table VII. shows the number of notifications of ophthalmia neonatorum received since the year 1914 in connexion with the work of the County Public Health Department under the Midwives Acts:—

TABLE VII.

Year.	Number of notified cases of ophthalmia neonatorum.	Total births registered.	Percentage of cases of ophthalmia neonatorum notified to total births.
1914	273	38,507	0·70
1915	234	34,595	0·67
1916	265	32,695	0·81
1917	233	28,420	0·81
1918	231	27,736	0·83
1919	323	28,799	1·12
1920	464	39,767	1·16
1921	265	36,558	0·72
1922	235	32,011	0·73
1923	208	30,672	0·67

It will be noted that the greatest incidence of ophthalmia neonatorum occurred in the years 1919 and 1920, the period of the demobilisation of troops.

[A table showing for three years the condition of the eyes after ophthalmia neonatorum was included. The figures were obtained by re-visits by the county staff. The table showed for the years 1919, 1920, and 1921 details of all eye cases and of those notified as ophthalmia neonatorum, and included information regarding condition of eyes after a lapse of from 2 to 26 months from the date of the first report, the following up of such cases being regularly made. In the year 1919, of 447 cases 323 were notified as ophthalmia neonatorum. In the year 1920 the corresponding figures were 665 and 464, and in 1921 436 and 265.]

On examination of the details obtained in the inquiries into ophthalmia cases the following facts were ascertained:—

Extending over a period of 6½ years: The average interval of time between the birth of the child and the onset of the disease (ophthalmia neonatorum) was 6·05 days. The interval between onset of disease and the date on the record sent by the midwife to the medical practitioner was 1·36 days. The interval between onset of the disease and the date of notification of the case, under the ophthalmia neonatorum regulations, was 4·29 days. The length of time between the date on the Medical Help Record (first report of the case) and the date a doctor first saw the child (commencement of treatment) was 1·25 days.

The investigations carried out by the inspector of midwives, health visitors, and assistant county medical officers show that many of the severe cases of ophthalmia neonatorum are due to gonorrhœa in the mother, but the data are insufficient to express as a percentage the incidence of gonorrhœa in notified cases of ophthalmia. I also receive certain information from certified midwives. It is their duty under the rules to call in a medical man in cases where they discover purulent discharge in pregnant women. There are 663 midwives practising in the county area at the present time, and the number of records received from midwives in respect of these conditions in the year 1922 for "purulent discharge" was 20. It is unlikely that these figures represent the true incidence of gonorrhœa in pregnant and parturient women attended by certified midwives, but medical practitioners inform me that they also see very few cases in pregnant and parturient women in the rural and small urban districts, and they further state that they see very few cases either in adult males or females. The assistant medical officers and health visitors report to me very few cases of gonorrhœa in females either at the infant welfare centres or during their home visits. It is my experience, therefore, that it is very difficult to estimate, with any approach to accuracy, the amount of gonorrhœa existing in women in the rural and urban districts of Lancashire.

TREATMENT OF WOMEN AND CHILDREN.

The provision of treatment for women and children suffering from venereal disease in a large county with 121 separate urban and rural districts is a difficult administrative problem. The problem in a large town is comparatively easy where there is a well-equipped hospital containing special departments for women, children, and persons suffering from venereal disease such as are seen in the large London hospitals. The gynæcologist seeing a case of venereal disease, or the physician in the children's department seeing a syphilitic child, can coöperate with the director of the venereal diseases department and through the lady almoner knowledge is gained of contacts to be followed up.

In the smaller districts of Lancashire there are either no hospitals, or they are not suitably equipped. The respectable married women generally will not attend the treatment centres provided in the large towns, nor will they take their children. In the textile towns a large number of the women are engaged in industry, and the wife of the coal miner is a hard worker. The provision and cooking of meals for perhaps several workers on different shifts, the care of their working clothing, and the bringing up of a family leave very little spare time for the coal miner's wife.

I think provision for the treatment of syphilis in women and children might be made in certain of the existing child welfare, antenatal, and school clinics where it is possible to make proper arrangements.

In one of the combined child welfare and school clinics in a small urban district in Lancashire I was able for a time to arrange for the treatment of syphilis in children. The final results were good. The numbers would not be large in any particular district, and the patients could be seen regularly by appointment. There could by this method be a close coöperation between school medical and child welfare medical officers, inspector of midwives, health visitors, school nurses, midwives, &c., and the venereal diseases medical officers treating the cases. Ophthalmic cases of syphilis in children, such as keratitis and choroiditis, should be treated by ophthalmologists.

The treatment of gonorrhœa in women in county districts is a much more difficult problem for the following reasons: (*a*) Gonorrhœa requires daily treatment; (*b*) it is not advisable from a surgical standpoint to treat gonorrhœa in the same department at which young children and babies attend; (*c*) there would be a danger of bringing the centre under the label "venereal."

The discovery of a specific treatment for gonorrhœa would simplify the administrative problem in county districts. It is the exacting nature of the present mode of treatment which creates the main difficulty.

A Lecture
ON
ACETONÆMIA AND VOLVULUS OF THE SMALL INTESTINE IN CHILDHOOD.

Delivered at the Hospital for Sick Children, Great Ormond-street, on May 15th, 1924,

BY F. JOHN POYNTON, M.D., F.R.C.P. LOND.,
PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL AND THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET.

MY subject is, I think, one of particular interest, not only on account of the extreme difficulty there is in clinical diagnosis, but because it touches upon the problem of acetonæmia in childhood, and introduces a group of cases which are of equal importance to the physician and surgeon. To discuss in detail all the aspects of acetonæmia would take me too far, and the particular cases I am dealing with will occupy most of our attention.

CONDITIONS OF OCCURRENCE OF ACETONÆMIA.

A lecture I gave in 1922, on diabetes in the young, dealt with one of the best known of all examples of acetonæmia, for, as you know, in childhood diabetic coma, which is acetonæmic in causation, marks the end of these cases. The usual symptoms you find then are the peculiar odour of the breath, air-hunger, intense weakness and drowsiness, and finally coma, with a urine which gives distinctive tests—namely, the purple colour that results from saturating 5 c.cm. of urine with an equal quantity of ammonium sulphate, and then adding a few drops of ammonia followed by a 5 per cent. solution of sodium nitro-prusside. This shows the presence of acetone and aceto-acetic acid. The purple colour on adding ferric chloride to the urine shows the presence of aceto-acetic acid. The other constituent, beta-oxybutyric acid, gives no easy clinical test. It is, however, only the most severe cases of acetonæmia that drift into the stage of coma; and it must be realised that a certain minor degree is a very frequent occurrence in many different disorders of childhood.

My colleague, Dr. R. Frew, published in 1911 the results of an examination for ketone bodies in the urines of 600 children admitted to hospital, and found their presence in 61·6 per cent. of all cases during the first three or four days after admission. He attributed the occurrence to change of diet, for it rapidly disappeared when the children had been longer in the hospital. I wonder myself whether nervous perturbation was a factor also.

We may for the moment look upon these two instances of acetonæmia I have mentioned, as at opposite poles. At one pole the frequent, mild, and indeterminate cases described by Dr. Frew; at the other, the fulminating cases of fatal diabetes. Between these poles we have various examples of its occurrence, including the remarkable group often called "cyclical vomiting." I have seen many striking examples of this most interesting disorder, in which acetonæmia is prominent.

A feature that has always impressed me in this group has been the extreme nervousness of these children, and quite a number of my cases have been the children of doctors. A considerable number have also been only children of very anxious parents, and in addition to a nervous temperament have been overfed with fats, eggs, cream, cod-liver oil, and such like. In fact, one finds oneself repeatedly attracted by two aspects in these cases—the irritable nervous system and deficient or overtaxed hepatic function. Some of these cases are fatal. I mean by this that a fatal and most puzzling illness may occur in which acetonæmia is prominent, and after death the explanation still remains a mystery. For example:—

A female child, aged 3 years and 3 months, was admitted to hospital in 1923, with a history during the last six months of recurrent attacks of vomiting, which had been labelled "cyclical vomiting." Six days before admission she had another attack in which she became restless and somewhat "demented." Next day she was better and then relapsed and became feverish, very restless, and wandering. On the sixth day she was admitted with staring glazed eyes, acetonæmic breath, much ketonuria, and rapidly became unconscious and died in collapse. All that was found after death was a slightly enlarged fatty liver and congestion of the cerebral meninges and brain.

In some acute infections, for example, influenza with pneumonia, acetonæmia may be prominent and associated with drowsiness and other puzzling symptoms. A condition of acetonæmia, which I have seen on more than one occasion prove fatal, may result from giving heavy doses of salicylate of soda to fragile children suffering from acute rheumatism.

In such cases there is intense general depression with a feeble pulse, and sometimes polyuria. The first serious symptom in my experience has been vomiting which is most intractable, then there supervene restlessness and the deep breathing which one associates with diabetic coma. This breathing becomes more intense, restlessness passes into delirium, and then into coma. The child eventually dies in coma.[1]

In delayed chloroform poisoning there supervene intense vomiting, the sclerotics may be slightly icteric, and the face rapidly becomes drawn with deeply sunken eyes. Restlessness and sighing respirations follow, the liver enlarges, and the child dies in coma. The urine shows abundance of ketone bodies, and the breath has the characteristic odour. Post-mortem examination and microscopy demonstrate intense destruction of the hepatic tissue.

There is still another group associated with volvulus of the small intestine, and in some of these cases the acetonæmia reaches such proportions as to dominate the diagnosis. It is a group in which starvation is a feature, and it is with such cases that my lecture is concerned. When the obstruction is high and vomiting is an urgent and early symptom acetonæmia becomes rapidly apparent, and the drowsiness, loss of strength, and extreme illness may then be attributed to a primary cyclical vomiting.

I do not think that starvation explains these symptoms, which are much more probably due to some intoxication brought about by the serious results of an obstruction high in the intestinal tract. Professor Gorter, in his recent lecture, attached much importance to the element of an acute intoxication in cases of obstruction high up in the alimentary canal. At first sight it would seem unlikely that an acute obstruction should be confused with, and lost sight of in, acetonæmia, but, as I shall demonstrate, these cases are remarkable in many respects, and we find ourselves held back by certain doubts which in the time of urgency come forcibly before our eyes.

I have already described a fatal acetonæmia in which there was little at the necropsy to account for death, and certainly no obstruction was discovered. An occurrence such as this is the cause of our grave doubts, for if in one of these cases of suspected obstruction you find no physical evidence of such obstruction you recall the fact that an acetonæmia may occur with the most urgent vomiting, and a sunken drawn face such as one sees in grave abdominal disasters and yet no striking lesion be found. Further, if the cause of this vomiting is of the mysterious nature met with in cyclical vomiting you hesitate to run the risk of an anæsthetic on the hazard of finding an obstruction which may not exist. I have known such an operation undertaken with negative results and fatal vomiting follow.

---

[1] Hurtley and Trevanion, working upon diabetic coma, suggest that diacetic acid causes coma in virtue of the creolic group it contains, $\begin{matrix}\text{COH}\\ \|\\ \text{CH}\end{matrix}$, and note that sodium salicylate also contains this unsaturated linkage.

Cases and Commentary.

The first case of volvulus I met with was a girl, aged 3 years, who was admitted to hospital on Dec. 4th, 1919, for vomiting and abdominal pain. She had been previously in the hospital for a similar attack with acetonæmia, and had been grouped in the class of "cyclical vomiting."

History.—The history was a very interesting one, for since the age of 1 month she had suffered from recurrent attacks of vomiting which occurred, with abdominal pain, half an hour after food. Each attack was accompanied by constipation and the appearance of an erythematous rash. In the first year she had three attacks lasting three to four days each, and later they had occurred at intervals of six weeks to two months. Between the attacks she recovered completely and was a healthy child. Previous to this admission she had been three times in hospital with the diagnosis on the first occasion of acute appendicitis (no operation was undertaken), and twice of cyclical vomiting. This attack commenced with malaise on Nov. 30th, 1919, and on Dec. 1st she vomited three times green and offensive fluid, and refused food. This continued for three days and was accompanied by constipation and abdominal pain.

Condition on Admission.—The patient was thin and looked ill, with flushed cheeks which somewhat disguised a muddy anæmia. The breath smelt of acetone and the tongue was furred. Neither the liver nor spleen was palpable. The abdomen was not distended and there was no rigidity. Fæces were felt in the lower bowel. The urine contained large quantities of acetone and diacetic acid.

Immediately after admission the vomiting stopped and the appetite returned. On Dec. 6th, when I saw her, she had vomited once and was still constipated, but now she looked well. She sat up in bed talking and taking interest, and had passed naturally a small offensive motion. The urine still contained acetone and diacetic acid. I thought, however, she had now turned the corner and would get well. On Dec. 7th she became quiet and drowsy with sunken eyes, vomited, and refused food. In spite of treatment with salines and glucose she remained in the same condition all day with a strong acetonæmic odour of breath. On the 8th she was worse, though an enema brought away a large offensive motion. In spite of this the suspicion flashed across my mind that there must be some obstruction, and this was supported by the development of some tenderness over the right upper quadrant of the abdomen, although nothing could be felt and there was no distension. In any case, unfortunately, my suspicion had come too late for she died that evening. Throughout the illness the temperature never rose above 98·4° F. The pulse in the last 24 hours rose in rate from 96 to 164 per minute.

The *post-mortem examination* showed the greater part of the small intestine to be gangrenous and to have an unusually long mesentery, which was twisted on itself clockwise through a complete circle. The cæcum and ascending colon were unusually mobile, but the remainder of the large intestine was normal.

Reviewing this case it seems a most remarkable one, particularly when you remember that the attacks, which precisely resembled one another, had dated from the first month of life. It appears to me that some partial rotation of the intestine must have continually recurred, but only in a sufficient degree to cause a partial obstruction. Then some movement of the intestine struggling against this difficulty, and possibly the effects of intense vomiting, righted the bowel again, for between times the child became quite normal. At least that is the only solution I can imagine. I can hardly believe that this was a cyclic vomiting in which a volvulus finally supervened, for sudden abdominal pain was one of the first of the recurrent symptoms in each attack.

By a strange coincidence within a week my house physician, Dr. J. C. Spence, told me that at St. Thomas's Hospital a similar case had occurred, and a volvulus of the small intestine had been discovered after death. I have no details of this case and must content myself with recording this statement.

For the next case I am greatly indebted to my colleague, Dr. H. Thursfield.

S. S., a male aged 3½ years, was admitted to hospital on Nov. 30th, 1922, for vomiting. There was nothing unusual in his history until he reached the age of 5 months, when he had an attack of vomiting and constipation, for which he was taken to St. Bartholomew's Hospital, and this was repeated at the age of 7 months. On Nov. 26th, 1922, the child refused a meal and commenced to vomit a thick green fluid, which later became watery. He wasted rapidly and was constipated, and there was considerable abdominal pain.

Condition on Admission.—He was admitted on the 30th. His breath smelt strongly of acetone. The abdomen was not distended, was normal on palpation, and not tender. He was constipated, but two results followed from enemata. The urine contained large quantities of acetone and diacetic acid. On Dec. 2nd he retained small quantities of fluid by the mouth, but in the evening he became delirious and very restless in spite of treatment with glucose and alkalies. On the 4th there was still vomiting and the temperature rose from 99° to 107° F. The pupils were unequal, the left the larger, and the knee-jerks and abdominal reflexes were absent. Death occurred that day. The diagnosis of acetonæmia was made as the most probable explanation.

At the *post-mortem examination* the small intestines were found almost black in colour, and there was a small quantity of fluid in the peritoneal cavity. The small intestine also was very mobile, and had twisted on its mesentery from right to left one and a half times. The left side of the mesentery was very deficient. The cæcum and appendix were lying below the splenic flexure and had a complete mesentery, and were also very mobile. The hepatic flexure was fixed.

Here again we find recurrent attacks of sudden pain, complete anorexia, green vomiting, constipation, and intense acetonæmia, but in this case apparently there had been no attacks between the ages of 9 months and 3½ years. The terminal symptoms of hyperpyrexia and delirium were only misleading. In my experience the great practical difficulty of a case such as this lies in the absence of any abdominal physical signs. There was here again no rigidity, no tumour, no particular distension, and yet the small intestine was gangrenous.

The next case is imperfect and inconclusive, but has considerable value in developing the points of difficulty that surround the subject.

S. A., a female aged 3½ years, was admitted to hospital on Dec. 5th, 1923, and died the same afternoon. Since birth she had been subject to attacks of vomiting and constipation at varying intervals. Two years before admission she had a severe attack, in which there was urgent vomiting and offensive breath, and in this she was "comatose" for some hours. There was constipation, but this was relieved by high enemata which brought away a large quantity of fæces, after which the child came rapidly out of coma and with a few days in bed completely recovered. She remained well until the final illness, which commenced on Nov. 30th, 1923, with constipation and vomiting. The bowels were well open on Dec. 1st and slightly on Dec. 2nd. On the 3rd she, a much petted child, was given in addition to her ordinary diet smoked haddock and meat, and that night there commenced incessant vomiting, which was at first green and later brown. On Dec. 4th she was comatose, and next morning a small motion was passed after a glycerine enema. That day she had apparently two tetanoid convulsions which quickly passed. On the 5th the vomit smelt fæcal and she was admitted here moribund, but rallied slightly after admission. Her eyes were deeply sunken and features pinched and white. The breath smelt strongly of acetone, and the urine was loaded with acetone and diacetic acid. Fæcal vomit was noticed on the pillow. The liver was large and firm, but nothing else abnormal was discovered. There was no optic neuritis. Dr. D. Nabarro found the blood-sugar was 0·02 per cent.; the cerebro-spinal fluid normal. She died at 2 P.M. Unfortunately, a post-mortem examination was refused.

I would point out that there was no history of abdominal pain in this case, but there were mysterious attacks of vomiting and constipation, extreme acidosis with breathing of the type met with in diabetic coma, and, most important of all, fæcal vomiting. The diagnosis must remain a secret, but it is impossible not to suspect that there must have been a high obstruction, and that the exciting cause was that unwise feeding just at the moment when the attack was apparently passing off. This possibly caused excessive peristalsis and a completion of the obstruction, which may again have been a volvulus of the small intestine.

The next case occurred this year.

The child, A. R. S., was a female aged 6 years 9 months. She was admitted on Jan. 8th for a condition of extreme acetonæmia.

History.—On Jan. 5th she vomited and had acute pain, doubling her up. The vomiting had continued until admission. The bowels were constipated and she had no appetite, but on admission to the hospital there occurred a fair-sized, rather constipated action. Her previous history showed that three years before she had an attack of abdominal pain and vomiting which lasted about 24 hours. The vomit was thin and greenish. Three months ago she had also another attack of vomiting with abdominal pain which lasted about two days. In both attacks there was constipation.

Condition on Admission.—The child was collapsed with sunken eyes, the breath, at first not acetonæmic, later became strongly so, and the urine was loaded with diacetic acid. Her general condition resembled that of the first fatal case I have already detailed. Her pulse was 100, resp. 24, temp. 98° F All food was refused, and when I first saw her there was vomiting of an inoffensive, green fluid. The bowels had been open once after a rectal injection of glucose. The motion was considerable and constipated.

The *diagnosis* was most difficult. The abdomen was not distended and nothing definite could be felt. The rectum was ballooned, but there was no tenderness or resistance. The child's condition was so desperate, and the memory of fatal cases of acetonæmia without explanation at the postmortem so imprinted on my mind, that I seized on the facts that the bowels had been open and the absence of any physical signs as indications to wait at least for a time before operation, and I did this after recalling and weighing for the first time the possibilities of a volvulus of the small intestine. Uneasy in my mind, I came down to hospital next day to find that the child was worse and that some remarkable changes had occurred.

There had been several large green vomits in the night, the temperature had risen to 100°, and the pulse was now 160 per minute. The abdomen had become distinctly distended in the upper segment, and I felt a resistance which was much in the position of the tumour of a pyloric stenosis but lying deeper and rather more indefinite. This made me conclude that there was an obstruction, though I felt that now I was almost certainly too late. Mr. O. Addison was in the hospital and he at once saw the case with me, and this time we noticed peristalsis of the stomach. We felt the only hope lay in an instant operation.

Operation.—On opening the abdomen the small intestines were found blue and collapsed, and herniated through a hole in the great omentum. They had also rotated clockwise round an axis in the position I had felt the resistance. This axis was at the duodeno-jejunal junction and was apparently formed by adhesions. The entire duodenum was greatly distended. The obstruction was rapidly corrected and the child for a few hours seemed to rally and did not vomit again, but suddenly collapsed and died five hours after the conclusion of the operation. Though I diagnosed the volvulus and located the axis of rotation before operation, this diagnosis was in reality more a successful guess than a reasoned opinion, but it is, I think, worth recording. Though too late, it served to break at least for me the paralysing influence of the word acetonæmia, and makes me hope that one day I may save one of these cases.

Here, again, we have recurrent attacks of abdominal pain, green vomiting, acetonæmia intense in degree, and constipation. This has been the only case I have seen in which abdominal examination was of the slightest assistance, but then, unfortunately, not until the condition was practically hopeless.

The next case is an illustration of the difficulty of the clinical aspect of the subject.

A. D., a boy aged 7 years, was admitted to hospital in May, 1922, for an acute attack of vomiting with extreme collapse, from which he made rapid recovery. Six months later he was again admitted for a similar attack, and again recovered rapidly. I have no intimate knowledge of these illnesses, but understand that a remarkable feature was the extreme degree of collapse. On Jan. 13th, 1923, he had a third attack and was admitted into the children's ward at University College Hospital. The attack commenced very acutely at night with vomiting, diarrhœa, and abdominal pain, and when admitted he was apparently moribund. His temperature was 96° F., he was almost pulseless, with respirations 40 to the minute. The attack terminated on the morning of the 16th. Physical examination was negative except for the discovery of much diacetic acid and acetone in the urine, and a liver just felt below the costal margin. The appearance of the boy was similar to that which you see in the worst attacks of cyclic vomiting. His recovery was rapid, the temperature rising for two days to 99°. Much care was taken in the diet, and in a few days he seemed quite himself. A week later, with no change in diet or treatment and while under supervision in the hospital, at 10.30 P.M. he vomited and passed a large watery motion. Two more such motions were passed in the early hours of the morning and within four hours he was in a state of complete collapse, with his breath smelling strongly of acetone and with acetone and diacetic acid in the urine, respiration was sighing, the features sunken, and the skin cold.

Again he recovered rapidly, but on the 27th, four days later at midnight, he had another attack with epigastric pains, but in this there was no vomiting or collapse. Next morning the abdomen was distended but not greatly, and there was no tenderness. Two days later, between 11 P.M. and 1 A.M., another attack occurred with vomiting, but of slight severity. The report by Dr. A. Salmond on a barium meal was as follows: "Œsophagus normal, stomach orthotonic, completely empty in six hours. Lower pole of cæcum mobile and not tender. Irregularity of distribution in small intestines suggesting adhesions." No further attacks occurred and he left the hospital in apparently normal health.

Six weeks later, at 5 A.M. on March 13th, 1923, he was readmitted in a state of extreme collapse. Temp. 96°, pulse 150, respirations 35 per minute. The respiration was sighing; the face blue and drawn; the limbs cold and acetone in the breath, and diacetic acid and acetone in the urine. The history was identical with other attacks. Sudden vomiting and three or four watery motions had occurred in the late evening. Once again he made a steady recovery, with some fever and constipation in the first few days. The stools showed a mixed growth of streptococci and *Bacillus coli*. Repeated physical examination led to no discoveries.

He was lost sight of until Jan. 14th, 1924, when he was admitted for headache, vomiting, and abdominal pain. This attack had commenced at midnight. His condition on admission was unlike that on previous occasions, for his temperature was 100°, and his abdomen was generally though not much distended. There was no tenderness and rectal examination was negative. Recovery was rapid.

He was said to have had during November and December, 1923, ten attacks of vomiting and diarrhœa. When I saw him he was perfectly comfortable and with a normal temperature.

I must admit that this case completely puzzled me. Though much investigation was made no tangible evidence of the cause of these attacks was forthcoming. There is, however, one point which is apparent in contrast to the preceding cases. Each attack was associated with a watery diarrhœa that resembled in its intensely depressive action the diarrhœa of cholera or sprue. Another feature in this case was the regularity with which the attacks commenced about 10 P.M. and usually ended in the early morning. Biased perhaps by my experience in the cases I have related, I decided that though the boy seemed well save for slight abdominal distension upon an exploratory laparotomy. Mr. G. Williams undertook this for me on Jan. 31st by an incision through the sheath of the right rectus. Masses of enlarged glands were found, though none of large size in the mesentery. The colon was rather loose. The small intestines had a curious tessellated appearance, such as I had seen in the previous case of volvulus, but there was no twist or band. The appendix was removed but was apparently not diseased and threw no light on the condition. The boy made an uninterrupted recovery, but I am not really wiser and shall fear further attacks. It is possible in this case that some partial rotation of the intestines takes place and causes some vascular obstruction with acute œdema of their walls as the result, rather than any sensible occlusion of the gut, but this is a pure hypothesis. The enlarged glands can hardly explain such a sudden and severe condition, and the absence of any blood in the stools seems to weigh against any ulceration of the bowels or intussusception.

The next case is in some respects the converse of the preceding one.

W. C., a male aged 11¾ years. He was in hospital in May, 1919, for three weeks at the age of 10 years 4 months, with a history of recurrent severe attacks of abdominal pain which caused vomiting and prevented sleep. These attacks had been recurring every six to eight weeks for the last 18 months. There were also outbreaks of diarrhœa in some of these attacks. He was a very thin boy with a doughy abdomen, in which were felt two coils of intestine which seemed matted together, and peristalsis of the intestine was occasionally noticed. His temperature varied between 97·8° and 99·4° F. Von Pirquet's reaction was negative. The final diagnosis was abdominal tuberculosis. There was no history of acetonæmia. In October, 1920, about

12 months later, he was admitted again with abdominal pain and distension, vomiting, and constipation. Some free fluid was detected in the abdomen, but he died shortly after admission.

The *post-mortem examination* was confined to the abdomen. The intestines were gangrenous, and were twisted contra-clockwise, two complete revolutions. The small bowel was "pinched off" about four inches above the cæcum. The blood-supply to the whole of the small bowel had been cut off. The mesentery was exceptionally long and free. There was about a pint of blood-stained fluid in the peritoneal cavity, but there was no evidence of abdominal or pulmonary tuberculosis.

Here was a case in which enlarged tuberculous glands and intestinal tuberculosis were suspected and in which there was a history of attacks of pain and vomiting with some diarrhœa, but the cause of death was a volvulus and there were no enlarged glands. The only other point was the absence of any evidence as to acetonæmia. The preceding case was acetonæmic and proved to have enlarged abdominal glands, but no volvulus was present at the time of operation.

A Developmental Explanation.

I should like to refer any who are particularly interested in these cases to a recent and valuable paper by N. W. Dott[2] on Anomalies of Intestinal Rotation. It is far too extensive and elaborate for me to do it any justice here. The writer commences with the embryology, and with the development of the fore-, mid-, and hind-gut. He points out that the lower end of the fore-gut (duodenum) soon becomes fixed, as also the hind-gut, the colic angle of which is early hitched up by a retention band. The duodenum and colic angle lie close together and between them is the mid-gut undergoing rapid development, on which account it herniates through the umbilical opening of the fœtus. There are three stages in the development in which rotation may occur in this loose unfixed gut, and it is the second stage which has special bearing upon our cases. In this stage the rotation is due to disturbance in the normal sequence of return of the contents of the umbilical hernia into the fœtal abdomen. Probably the disturbance is concerned with the return of the cæcum into the fœtal abdomen, which instead of doing so last, does so first or together with the small intestine through an unusually large opening. There result various mesenteric adhesions, imperfect fixation, a mobile cæcum, or an abnormally narrow pedicle to the small intestine up to the fixed duodenum.

Dott illustrates a volvulus of the whole small intestine clock-wise as a result of malposition, and points out the importance of these abnormalities as a cause of obstruction soon after birth. Volvulus, he remarks, is the most frequent lesion on account of (1) an unduly narrow base to the loop of intestine; (2) undue length of the mesentery; (3) a point of adhesion at the convexity of the loop which acts as an axis of rotation. He mentions as exciting causes (1) unusual effort; (2) peristaltic mobility of the intestine; (3) undue distension of the stomach.

Conclusion.

My treatment of the subject is obviously imperfect and betrays the wanderer finding his way with uncertainty. The lesson it teaches is, however, clear enough, and is that we must beware of being content with the diagnosis of acetonæmia in young children when there is a history of abdominal pain and partial constipation, even though that acetonæmia be intense and physical examination of the abdomen negative. It may be wondered why I have included the case without volvulus, a case for which I can give you no satisfactory explanation; but my reasons are that the diagnosis that was made was cyclic vomiting and acetonæmia until the attack under observation in hospital seemed to exclude this suggestion, and the case itself is an example of the intense clinical difficulty that surrounds these acute attacks.

It is clear that acetonæmia is in childhood a symptom that may occur under very different conditions. Very frequently it is noticed as a fleeting event in an illness and, so far as one can judge, does not perceptibly alter the outlook, though there may be some unusual drowsiness, muscular feebleness, or cerebral symptoms. If persistently looked for, it may be recognised as an event which may have no serious clinical significance at all, as in Dr. Frew's series. In other cases, as in diabetes, it may have the greatest importance as a danger-signal. In yet others it may be the prominent feature in a recurrent illness which may, though rarely, prove fatal, and in which after death we may find no changes in the viscera, the liver possibly excluded, that can satisfy us as to the cause of death. Finally, it may prove a cause of grave errors in diagnosis, by its prominence in cases such as I have detailed here. Certainly it is not alone responsible for this error, the other factors being the absence of abdominal physical signs, the occurrence of only partial constipation, and the history of repeated attacks with complete recovery between times.

The obvious moral is, in our present state of knowledge, never to regard acetonæmia in childhood as a disease, but always as a symptom.

I must express my indebtedness to Mr. S. I. R. Chadwick, my late house physician, for great assistance in collecting the data which form the basis of this contribution.

SOME CASES OF
ALEUKIA OR APLASTIC ANÆMIA
ASSOCIATED WITH THROMBOPENIA.

By S. C. DYKE, M.D. Oxf., M.R.C.P. Lond., D.P.H.

(From the Pathological Laboratories of the Clinical Units, St. Thomas's Hospital.)

This communication is intended to draw attention to some blood pictures presenting unusual features; the clinical conditions of which these pictures formed a part conformed in general to what in this country usually goes by the name of "aplastic" anæmia, and which has been called by Frank,[1] and after him by other continental workers, "aleukia," indicating by this an actual and relative decrease of the polymorphonuclear leucocytes. This decrease of the polymorphs gives the condition its name, but it is associated with other peculiar features, among the most striking and important of which is a decrease in the platelets; it is known from the work of Bedson[2] and others that a withdrawal of the platelets from the circulation in experimental animals is associated with purpura and hæmorrhage, and it is this deficiency of the platelets which is supposed to account for the hæmorrhagic tendency shown by cases of the aleukic type. In America, Duke[3] has produced clinical evidence in support of this view. In the opinion of Frank and his followers, the condition depends upon a primary deficiency of the hæmatopoietic system, and Frank has even laid it down that, when evidence of infection appears in the face of the blood picture of aleukia, the infection must be regarded as secondary to the damaged state of the hæmatopoietic system. Three of the cases to be described afforded evidence of infection; clinically all were characterised by a diminution, both actual and relative, of the polymorphs and by a hæmorrhagic tendency; in all in which observations were made the platelets were markedly deficient.

Case 1.—The patient, a male, aged 36, suffered from "influenza" in February, 1922; thereafter noted increasing pallor; in March experienced an attack of pain in the right knee, which persisted for a few days; from that time on similar attacks of pain occurred at intervals of two or three weeks in one or both knees, always unattended by swelling or other visible evidence of inflammation. In June the pain in the knees became so severe that the patient took to his bed. Thence onwards the pallor increased. Early in August a purpuric rash appeared on the left arm, and there was bleeding from the gums on brushing the teeth. On admission in August, 1922, the patient was very pale; petechial spots were present on various parts of the body and limbs ; the spleen was palpable and tender. The only complaint was of pain in the knees and weakness.

Patient remained in hospital until April, 1923, during which time there was little change in his general condition. The attacks of pain in the knees continued at intervals of a few weeks, being usually accompanied by an evening rise of temperature for several days in succession. Between the attacks the temperature was normal and the patient quite comfortable. Slight bleeding from the gums was persistent, and there were occasional outbreaks of petechial rash. From Dec. 16th, 1922, to Jan. 9th, 1923, the patient was treated with stabilarsan intravenously, receiving 2·2 g. intravenously in 15 doses. Otherwise treatment was by arsenicals by mouth. In April patient left the hospital at his own request; death occurred in August ; there was no autopsy.

Results of examination of the blood were as given in Table I. In many instances examination of the blood films revealed some degree of anisocytosis and poikilocytosis ; a slight degree of polychromatophilia was also present ; nucleated red cells were present to the extent that 2 to 3 were usually encountered in counting 100 white cells. In spite of these findings, and in accordance with the observation that the colour-index never rose above unity, pernicious anæmia was ruled out in the diagnosis by the fact that examination of the gastric contents after a test-meal showed free HCl to the extent of 0·073 per cent. and combined to the extent of 0·033 per cent.

A most striking feature of the blood picture in this case was the " aleukia "—the great diminution, both relative and absolute, of the polymorphonuclear neutrophiles. The intermittent temperature and enlarged spleen both suggested an infective process—though both are reported by Frank in his cases of aleukia.

In the next case an infective process certainly played a part, though how far as a cause and how far as a result of the aleukia is open to discussion.

CASE 2.—Female aged 50, married, five children; rheumatic fever at age of 30. In December, 1922, the patient had a severe attack of pain in the left loin. In April she experienced a second attack of a like nature, lasting for some days. From that time on until her admission on Sept. 1st, 1923, the attacks recurred at intervals of a few weeks, and she became steadily worse and more run down.

Condition on Admission.—The patient was pale, and complained principally of a rather ill-defined pain in the back, which was tender to touch. Tenderness was elicited on deep pressure in the abdomen, but palpation revealed nothing abnormal. Shortly after admission the site of the pains moved to the upper arms and thighs. At first it was impossible to identify the nature of the pains, but as the condition advanced, it became obvious that they were located in the bones. In spite of the exhibition of iron and arsenic, the pallor steadily increased and the patient became increasingly asthenic. On pricking the ear for the blood examinations detailed below, bleeding continued for some 15 minutes to half an hour, a very marked prolongation of the bleeding time. In October the spleen became palpable and thereafter steadily enlarged ; at this time also hæmorrhage, never severe, but almost continuous, started from the nose and continued until death. On the 15th, venipuncture was performed for the purpose of cultivating the blood ; on applying a rubber band around the arm just above the elbow for the purpose of producing venous engorgement a large and striking crop of purpuric spots appeared in the antecubital fossa distal to the constricting band ; this was the only purpuric manifestation. The blood culture itself was negative.

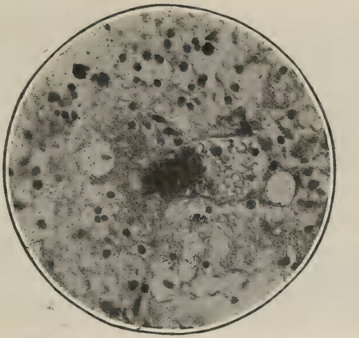
During the whole of her stay in hospital the patient ran an irregular intermittent temperature ; at first it never rose above 101° F. and there were long apyrexial periods ; during the last two weeks of life, however, it became continuous, rising as high as 104° in the evenings.

The result of blood examinations was as shown in Table II.

Autopsy.—At autopsy, save for considerable fatty change, all the organs except the spleen, which was enlarged, and the bone marrow, appeared normal. It had been anticipated that the bone marrow throughout the body would be of the greyish colour and dry consistency usually met with in the aplastic anæmias, and this was the case so far as that of the ribs, sternum, diploë, and right ulna were concerned. The only other bone of which the marrow was examined was the left femur ; the shaft of this bone contained a deep red, jelly-like tissue, very different from the contents of the medullary cavities of the other bones examined, and also very different from the opaque, maroon-coloured marrow usually found in the same site in pernicious anæmia.

On microscopic examination it was obvious that the peculiar appearance in the marrow of the femur was due to hæmorrhage within the medullary cavity. Sections showed no hæmatopoietic tissue, but masses of red cells in process of disintegration, together with much formation of fibrin. The picture was that of a fairly recent hæmorrhage, in which the hæmoglobin was in process of being dissolved out of the red cells, but in which definite organisation had not yet commenced. Further examination showed clumps of streptococci lying in the hæmorrhagic areas, for the most part in what was left of the sinuses of the marrow (Fig. 1).

FIG. 1.



Case 2.—Streptococci in marrow of femur.

Microscopic examination of the spleen showed very similar appearances—masses of effete red cells, fibrin formation, and the presence of clumps of streptococci. Streptococci were also demonstrated in the sinuses of the liver, though here they were unaccompanied by extravasation of blood, and were presumably due to terminal spread by the blood-stream.

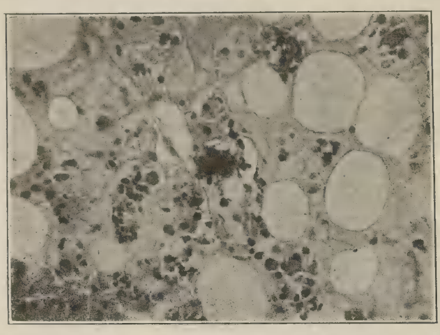
Taken in conjunction with the fact that severe gnawing pains had existed in the shafts of the long bones for weeks before death, these post-mortem findings are of considerable interest. The presence of the hæmorrhages would seem to offer an explanation of the pains and the presence of the streptococci an explanation of the hæmorrhages. The presence of hæmorrhages and of streptococci in the spleen offers an explanation of the enlargement of this organ, and the fact that this enlargement made itself apparent some weeks after the onset of the bone pains suggests that the invasion of the spleen was secondary to that of the bone marrow. It seems probable that, could an examination of the lumbar vertebræ have been made post mortem, an explanation of the early lumbar pain might have been forthcoming along the same lines. The fact that quite late in the condition culture of the blood was negative, together with the fact that post mortem the heart valves were found to be unaffected, indicates that, except as a terminal event, at no time was the passage of organisms into the blood-stream very free.

CASE 3.—Male aged 19. No past history of importance. Onset on May 27th with headache, sore throat, and swollen glands ; two days later bleeding commenced from the throat. On June 2nd patient was removed to a fever hospital ; while there the bleeding continued from the throat and also occurred from all other mucous surfaces. The tonsils were ulcerated, but no glands were now palpable. A petechial rash appeared on the mucous membrane of the mouth and on the skin of the arms and trunk. The temperature ran as high as 103° F. On June 8th patient was admitted to St. Thomas's Hospital ; on the same day he received a transfusion of 900 c.cm. of citrated blood.

Blood count : Hb below 20 per cent. ; red cells, 1,400,000 ; white cells, 200. White cells nearly all lymphocytes ; platelets very scanty. Death occurred on June 11th.

Autopsy.—Body showed purpuric spots on arms, chest, and abdomen ; in the abdominal cavity the mesentery showed purpuric patches, and there was a large hæmorrhage around the lower pole of the right kidney ; the spleen was large, firm, and very dark ; the liver was large, soft in consistency, and in colour dark red mottled with yellow ; the yellow mottling was due to necrotic patches throughout the organ. The heart muscle was soft, the valves were normal. The bone marrow of the femur was dark red and semi-liquid. Microscopic examination of the liver showed the yellow patches to be areas of focal necrosis; numerous coliform organisms were present in the sinuses throughout the organs; similar coliform organisms were demonstrated in section of the spleen and the marrow from the femur (Fig. 2), and in both these situations abundant hæmorrhages were evident.

FIG. 2.



Case 3.—Coliform organisms in marrow of femur.

CASE 4.—Male aged 34. Originally a typical case of myeloid leukæmia; swelling of the spleen was first noticed in July, 1923; patient was admitted to hospital during the same month, his blood then showing a white count of 121,000 per c.mm. He received a number of applications of radium to the spleen. In October he commenced to run an irregular pyrexia, which continued until death. His white counts were as follows: Oct. 22nd, 28,000 per c.mm.; Nov. 6th, 34,000; 24th, 5700; Dec. 13th, 2800. At this time a petechial rash appeared on the back and hæmorrhage occurred from the mucous membrane of the nose and throat. Death occurred on Dec. 16th.

Autopsy.—This case showed a miliary tuberculosis. The only unusual feature was the fact that in the only bone examined, the femur, the marrow showed extensive involvement in the tubercular process. A section of the bone marrow is shown in Fig. 3.

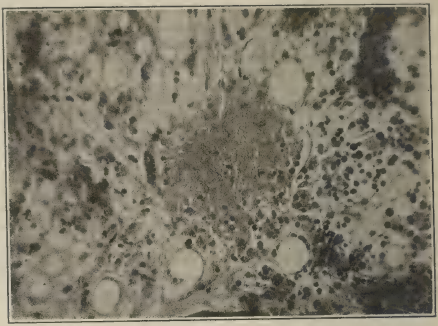
— Indicates no observation recorded. * After discharge from hospital.

Here are, then, four cases the principal features common to all of which are anæmia, a hæmorrhagic tendency, and leucopenia, associated in those cases in which observations on the point were made with a relative and actual diminution of the polymorphs and a disappearance of the platelets. In three of these cases it was possible to demonstrate an infection of the bone marrow after death—in one case streptococcal, in one due to a coliform bacillus, and in the last tubercular. There are good grounds for believing that such a septic condition of the bone marrow would also have been found in Case 1 had examination been made. On the face of it, it would appear reasonable to attribute the blood picture and the clinical condition to the infection of the bone marrow. Some doubt is thrown upon this interpretation by the next case to be described.

FIG. 3.



Case 4.—Tubercle in marrow of femur.

CASE 5.—Female aged 53. Always had tendency to bruise rather easily; menstruation usually excessive until cessation. In January, 1923, one of her eyes became "black" without any known previous trauma, at the same time petechial spots appeared on the gums and lips. In April, 1923, a tooth was extracted; the bleeding continued for five hours, until the socket was plugged and oozing continued for some time after this. Thereafter she became very pale. Since January she had bruised even more easily than usual, and had had several outbreaks of purpuric spots on the feet and legs. On admission in May, 1923, the patient showed numerous bruises all over the body and limbs, ecchymoses were present on the gums and purpuric patches on the feet and legs. The spleen was not then palpable. Blood counts in this case were as shown in Table III.

Notes on Blood Counts in Table III.—May 20th, 1923: Some anisocytosis and poikilocytosis of red cells, but no nucleated forms seen. Notable diminution of the platelets; many "giant" forms present. June 13th: Platelets very deficient. 20th: Some anisocytosis and poikilocytosis, but not so marked as previously. Platelets still very scanty; "giant" forms still present, but not so numerous as in previous observation. Dec. 10th: Anisocytosis and poikilocytosis still present.

On all occasions on which blood was taken for examination the hæmorrhage following the necessary prick was very prolonged, indicating a greatly increased bleeding time. While in hospital this patient developed a crop of petechiæ all down the left side, on which she was accustomed to lie while in bed. Otherwise the course was uneventful, and, as will be seen from the blood counts given above, her condition steadily improved. There was no overt hæmorrhage at any time, but occult blood was present in the stools. Examination of the stomach contents after a test-meal showed free HCl 0·09 per cent., and combined 0·01 per cent. The patient was discharged in July and seen again in December, 1923, and March, 1924. On the last examination she complained of pain in the left side, and on examination the spleen was found to be enlarged and palpable. She stated that she still bruised readily, but otherwise appeared to be in fair health.

In this case the condition of aleukia, so far as the observations go, seems to be inherent, though subject to fluctuation. The blood picture shows the same features, though to a less marked degree, as in Cases 1–4, and would seem to indicate an inactive condition of the hæmatopoietic system. It is not difficult to believe that such a hæmatopoietic system would offer but little resistance to infection and that in the face of an infective agent, no matter of what nature, the patient might readily pass into the condition illustrated by Cases 1–4. Case 4, indeed, affords an instance of a damaged hæmatopoietic system being attacked by an infection—the noxa being supplied in the first instance by the leukæmic condition, and in the second by the radium treatment—while the infective agent in this instance was the tubercle bacillus. I have seen one other case, of which, unfortunately, I have no notes, identical in every way, except that the patient was a woman, and X rays were used in treatment instead of radium. In this case I was able to demonstrate a streptococcus in the bone marrow.

These last two cases, in which the infection of the bone marrow is known to have occurred in the presence of pre-existing damage, seem to afford some evidence for the belief that in all the cases described the bone marrow may have been in an unhealthy condition prior to its infection. The fact that in Case 1, in such bones as were examined and the marrow of which was not the seat of an infective process, the marrow was of the dry, colourless appearance usually associated with anæmia of the aplastic type, also appears to afford some evidence that in this case at any rate the myelophthisic condition was primary to the infection.

Myelophthisic Condition giving Rise to Blood Picture of Aleukia.

Of the myelophthisic condition giving rise to the blood picture of aleukia, Frank recognises three degrees.

1. *Intermittent Thrombopenia.*—This condition manifests itself clinically by occasional recurrent attacks of hæmorrhage and purpura; it is seen mainly in children, and embraces those conditions now variously known as purpura hæmorrhagica, peliosis rheumatica, Henoch's purpura, and so forth; it may also occur in adults. Frank states—and his view is confirmed by such other writers as have given attention to the matter—that, prior to the onset of the hæmorrhagic manifestations in these cases there is always a diminution in the platelet count, though between attacks this is normal, and some degree of leucopenia with an actual and relative decrease of the polymorphonuclear neutrophiles. The present writer has only had the opportunity of investigating one case of this kind: in it the platelets were reduced to 50,000 per c.mm.

2. *Essential Thrombopenia.*—The condition just described is characterised by its intermittency and by a tendency to disappear. In some persons, on the other hand, it may last for long periods or throughout life. Such persons bruise readily and may at times have attacks of purpura or hæmorrhage of greater or less severity. The blood picture shows anæmia, a reduction in the platelet count, leucopenia of varying degree, and a diminution in the polymorphonuclear neutrophiles, both relative and absolute. Case 5 above would fall under this head.

3. *Aleukia Hæmorrhagica, or Aplastic Anæmia.*—An accentuation of the features described above will show itself clinically by severe anæmia, purpura, and hæmorrhage. Except for the accentuation of all the features the blood picture will be the same as described already. In the most severe cases the hæmorrhage may be intense and the downward progress rapid. Cases 1, 2, and 3 above would fall under this head, with the infection as a superadded phenomenon.

It will be seen from the above that Frank has attempted to bring together within one concept a number of clinical conditions not now regarded as necessarily related. He does admit that typical aplastic anæmia may arise as the result of the activity of certain poisons, citing in this connexion the experimental work of Bunting[4] with benzol, and also the effect of X rays; Case 4 above would be one of these cases due to a specific noxa. Leaving these cases aside, however, he maintains the existence of aleukia as an entity (wohlumschriebene Krankheit).

The counts of the platelets given above were made by counting the platelets against the red cells in 2 per cent. sodium citrate in normal saline solution. A drop of this solution was placed upon the nail bed of the patient's finger and puncture made through the drop, the drop of blood and solution being then received into a 1 c.cm. bulk of the solution in a paraffined agglutination tube. The actual count was then made at leisure in the laboratory. This method can only be regarded as approximate. With normal persons the count usually comes out at 250,000 to 350,000. A count of below 100,000 is looked upon as indicating a definite thrombopenia.

My thanks are due to Prof. H. MacLean, Director of the Medical Unit, St. Thomas's Hospital, and Dr. C. R. Box, of St. Thomas's Hospital, for permission to publish cases; to Dr. Coulter, of the Police Convalescent Home, Hove, for notes on the progress of Case 2 after the patient had left hospital; and to the Medical Research Council.

THE INDICATIONS FOR OPERATIVE TREATMENT IN CASES OF PULMONARY TUBERCULOSIS.*

BY H. MORRISTON DAVIES, M.D., M.CH. CAMB.,
F.R.C.S. ENG.,

MEDICAL SUPERINTENDENT, VALE OF CLWYD SANATORIUM; CONSULTING SURGEON, UNIVERSITY COLLEGE HOSPITAL, CITY
OF LONDON HOSPITAL FOR DISEASES OF THE CHEST,
AND KING EDWARD VII. WELSH NATIONAL
MEMORIAL ASSOCIATION.

A REAL interest in the surgical treatment of pulmonary tuberculosis is at last stirring in this country, roused by the visits of foreign surgeons with big experience. Though I have been doing the various thoracic operations for the last 12 years and more, it has only been possible during the last two years or so to get the work properly organised. Since then, however, the work has proved so stimulating, and the results so encouraging to those who have watched the cases, that a greater general desire for knowledge on this subject has developed in the Association. For this reason I have been asked to define the type of case fit for surgical intervention. Under the terms "surgical treatment" and "surgical intervention" I am including artificial pneumothorax; but this does not mean that I consider pneumothorax should be done by the surgeon. "Surgical treatment" is utilised as a convenient term for referring to certain forms of special treatment as opposed to treatment by graduated exercises and the use of vaccines.

It is tempting, in passing, to speculate on the changes that will have to come about in sanatoria built for treatment by graduated exercises. A time will come when the public will expect that the surgical methods which are proving so triumphant shall be available for rich and poor alike. It will mean the addition of operating facilities as well as X rays, an increase in nursing accommodation and of nursing and medical staff. In the majority of institutions the staff is inadequate in numbers, even for pneumothorax treatment, on anything like the scale on which it should be used; it is wholly inadequate if surgical treatment is made available for all those cases for whom it is suitable.

---

* Delivered before the Welsh National Memorial Association at Llandrindod Wells.

Cases under Personal Observation.

In my own sanatorium, out of 30 patients seven are having pneumothorax treatment. Of these, one is having a bilateral pneumothorax; the right side was started three years ago and adhesions had to be divided to obtain complete collapse. The left side was started two years ago. One is an advanced unilateral case who has been under treatment at various places since 1919; pneumothorax had not previously been suggested. It is nine months since I started; his cough and sputum are reduced to a negligible amount and the rectal temperature, which was averaging 101° F. at nights, is now not higher than 99°. A third case is a young woman who came in with considerable bilateral disease. Her evening temperature during the first three months varied between 100° and 102°. Absolute rest had no effect on her temperature and she lost weight, but the signs on the least affected (right) side subsided sufficiently to allow me at last, and in desperation, to start a pneumothorax on the left side last June. By the middle of July her temperature had started to drop. Although her pneumothorax is most incomplete, her evening temperature (rectal) has, during the last eight months, averaged 99°. She can now walk three miles and has gained 24 pounds in weight. A fourth case was admitted with a pyopneumothorax following on artificial pneumothorax. The liquid has been repeatedly replaced by oxygen but re-accumulates. I propose doing a thoracoplasty on him.

I am going to attempt a pneumothorax on three others; on one of these, if it fails, a thoracoplasty will have to be done. On three of the patients here at present a pneumothorax was tried and failed. On one of these I did a thoracoplasty, after trying ordinary treatment for eight months without success. She, from the day of the operation (eight months ago), has had neither cough nor sputum, although she had had both persistently for two years prior to it.

Aim and Method of Production of Collapse.

The aim and object of all varieties of surgical intervention in suitable cases is to obtain collapse of the lung in order to (1) rest the lung—as one does a tuberculous joint; (2) obliterate cavities and produce approximation of their walls—as one does with all infected cavities, when possible; (3) compress the lung and so prevent bleeding; to this may be added (4) put the lung out of action to abolish dyspnœa. It is generally understood that with the rest, obliteration of cavities and compression obtained by collapse, the symptoms, cough, expectoration, and bleeding, together with those symptoms due to the secondary infections, are diminished or abolished according to the extent of the collapse of the lung and the limitation of the disease to the one side. But it is not so generally realised that dyspnœa is a symptom dependent far less on the extent of the loss of functioning lung substance than on the interference with the relative freedom of expansion of the lung and the chest wall. Dyspnœa may be more marked in a comparative early case of unilateral fibrosis which is hindering expansion of the lung while the corresponding side of the chest wall is moving freely, than it is in a more advanced and bilateral case in which the movements of the chest wall have become restricted and are therefore, at each respiration, attempting to produce much less expansion of the lungs.

Collapse may be produced (*a*) of the whole lung, by pneumothorax, in the absence of adhesions; or, if adhesions are present, by thoracoplasty—i.e., partial decostalisation resulting in collapse of the lung and chest wall; and (*b*) of part of the lung, by pneumothorax, when adhesions are preventing total collapse; or by apicolysis—i.e., collapse of the upper lobe together with the parietal pleura, the space thus formed being filled in by some foreign body.

A local partial collapse of the base can also be obtained by phrenicotomy and consequent paralysis of one dome of the diaphragm; localised partial collapse results also from a localised thoracoplasty. So much simpler and less severe is pneumothorax than thoracoplasty, or even than apicolysis, that this method must always be the method of choice when practicable. With a total pneumothorax and the absence of adhesions, over 70 per cent. of the cases so treated become fit to return to work. The presence of adhesions, however, reduces this favourable result to as low as 11·1 per cent. when the adhesions are extensive. Adhesions can be divided, however, and whenever a partial pneumothorax can be converted into a total one by the division of adhesions, this must always be done.

A Classification of Tuberculosis from a Surgical Standpoint.

Having thus sketched in briefly what is the aim and object of surgical treatment, and the means by which that object can be obtained, I am in a position to indicate the types of case suitable for this treatment. To make this easier I am going to classify tuberculosis in a manner which physicians doubtless will consider most unorthodox.

A. *Acute Tuberculosis:* (1) Miliary, (2) pneumonic.

B. *Chronic Tuberculosis:* (1) *Early Stage.*—During this stage the fibrosis is nominal and the retraction of the lung due to it is easily compensated by collapse of the chest wall, displacement of the mediastinum, and emphysema of the healthy parts of the lungs. In this early stage secondary infection, though probably present to a slight degree, produces no recognisable distinctive symptoms.

(2) *Fibrotic Stage.*—The amount of fibrosis and the contraction of the volume of the lung due to it has passed beyond the limits of compensation. The pathological mechanical factors are appearing on the scene; the bronchi are becoming in places constricted, in others dilated; retention of secretions is beginning. Secondary infection is established, but is not yet of supreme importance. The symptoms are in part due to the secondary infection, but the tuberculous infection and the symptoms due to it (together with the dyspnœa due to the fibrosis) are still predominant. This stage is a transition stage between 1 and 3, but it undoubtedly deserves a class to itself, although the transition from stage 1 to 2 and stage 2 to 3 are unrecognisable. In cases with a moderately good resistance to the disease this stage may be very protracted.

(3) *Bronchiectasis and Cavity Formation Stage.*—The pathological mechanical factors are pronounced; dilatation and distortion of the bronchi and bronchioles or the presence of single or multiple cavities in the lung parenchyma are associated with a degree of retention of secretions and of secondary infection that alters the clinical picture in a very decided fashion. This is particularly the case when the secondary bronchiectasis is established; the clinical picture of tuberculosis may be completely obscured by that of bronchiectasis. The condition of the patient is serious: failure of nutrition and a high, swinging temperature are added to the picture.

Such, then, is my classification of pulmonary tuberculosis from the surgeon's standpoint. To it must be added that hæmorrhage may occur in any stage of the chronic variety. In the first stage it is never serious; in the second stage it may be alarming owing to its persistency, or distressing because of the frequency of the recurrence of the bleeding; in the last stage it may be immediately fatal.

Indications for Surgical Intervention.

I am now able to describe in what types of cases surgical intervention is indicated. I have already stated that of the three methods, artificial pneumothorax, apicolysis, and thoracoplasty, neither of the two latter should, as a general rule, be used when a complete pneumothorax is possible; and that if a pneumothorax is incomplete owing to adhesions, these adhesions should be divided if they are of that kind which lend themselves to it—i.e., are in the form of bands.

The acute miliary form of tuberculosis is practically always bilateral and is unsuitable for surgical treatment. The pneumonic form, on the other hand, is often unilateral. If it is entirely unilateral, then, unquestionably, pneumothorax offers the greatest hope of success. In this type, even if no adhesions are present, it will take a long time to collapse the lung because it is consolidated, and absorption of the pathological products takes a long time. Should adhesions prevent the production of a pneumothorax, thoracoplasty is not indicated, as the condition of the patient is too grave to stand such a serious operation. If, however, the pneumothorax is limited at the base by adhesions between the lung and the diaphragm, the phrenic nerve can be divided in the neck under local anæsthesia so as to paralyse that dome of the diaphragm and assist in the collapse of the base.

Chronic Pulmonary Tuberculosis: Stage 1.—I have said as regards this stage that it is one in which the fibrosis is so little that it can be compensated by the body itself, and, as there are neither cavities nor abnormally dilated spaces, the disease can heal completely if the resistance of the patient is moderately good and can be sufficiently improved. Surgical intervention is not, therefore, a *necessity;* on the other hand, the greater my experience the more emphatic do I become in my assertion made first some years ago now, that no case of pulmonary tuberculosis which has been diagnosed with certainty is too early a one for treatment by artificial pneumothorax, provided there are no contra-indications. I have never regretted doing an artificial pneumothorax in an early case, but I have often regretted not doing one. Let me at once add, however, that if artificial pneumothorax fails, no more severe line of treatment is justifiable.

My reason for this axiomatic statement is, that it is very difficult to gauge the resistance of a patient. I have frequently been deceived by the mildness of the disease, by the general good appearance of the patient, or by the rapidity with which the signs clear up under ideal conditions, into thinking that healing will progress rapidly and is likely to be maintained, only to find disappointment in the slowness or absence of recovery of control or the ease with which the disease reasserts itself at the first relaxation of routine treatment.

In the selection of cases at this stage for artificial pneumothorax there are certain considerations in addition to the ordinary contra-indications which have to be weighed very fully. In the more advanced cases in which pneumothorax treatment may be the determining factor as to whether the patient lives or dies, the future problem of time and expense for the refills over a period of two, three, or more years is of less serious import. But in these "early" cases the patient expects—and rightly so—to be able to return to work. If he is in a subordinate position—e.g., in an office or in the army—the leave required for these refills might seriously prejudice his position. It requires, moreover, much greater confidence on the part of the medical man to advise, and of confidence of the patient in his medical adviser to accept the recommendation of artificial pneumothorax at this period in the course of the disease.

As we shall see when we come to the contra-indications, the temperament of the individual may be an important factor in deciding against pneumothorax treatment. In these early stage cases still greater weight must be attached to the inadvisability of active treatment in a patient whose temperament is not absolutely satisfactory.

In stages 2 and 3 surgical intervention is always indicated when practicable. In stage 2, particularly when it is not far advanced, it is possible to get good results by sanatorium treatment, and the patient may, if fortunate, continue to keep well. It must be remembered, however, that the lung is not only scarred, but that also the fibrous tissue is under unfavourable conditions because it is always under tension, the fibrosis having increased beyond the stage of adequate compensation. Moreover, changes have already begun in the bronchi and bronchioles, and these have become much more susceptible to infection and reinfection. Once the patient has reached stage 3 nothing but a very partial and very temporary improvement—if that—can be effected by sanatorium treatment or by tuberculin or by any line of treatment which does not result in collapse of the lung and its dilated spaces. It must be remembered, moreover, that once stage 2 is definitely established it is probably rarely possible to keep the patient constantly free from infection, which means that he is constantly more or less a danger to other members of the community. Until stage 2 is reached, artificial pneumothorax with, if necessary division of adhesions, and perhaps phrenicotomy, is the only justifiable method of surgical intervention. But with the advent of stage 2 apicolysis and thoracoplasty have to be considered as alternatives when artificial pneumothorax is impracticable. If the disease has reached stage 3, thoracoplasty is the only alternative to a complete pneumothorax. The choice between apicolysis and thoracoplasty rests entirely on the extent of the disease. Apicolysis should be confined to those cases only in which the disease is limited to the upper lobe. It is eminently suitable to that form of chronic disease in which one sees radiologically the upper lobe extensively fibrosed and sharply delineated from the middle or lower lobe.

Hæmorrhage may occur in any stage of the disease, and is always an indication for artificial pneumothorax unless there are contra-indications. The peace of mind obtained for the patient when he or she can be assured that bleeding is no longer to be feared is, in itself, sufficient to justify the treatment.

Contra-Indications.—The contra-indications to pneumothorax and thoracoplasty are much the same, except that for the major operation they are somewhat more stringent and more rigid. It is easily understandable that albuminuria, glycosuria, and intestinal tuberculosis are such unfavourable complications that to embark on surgical treatment when any of these are present would be most unwise. Laryngeal tuberculosis, on the other hand, is not a contra-indication unless very advanced and associated with extensive ulceration or involvement of the epiglottis. Advanced intestinal stasis and nervous or neurasthenic temperaments are likely to interfere with the success of surgical treatment. The danger with stasis is in the violence of the reactions it may give rise to after refills with gas, and the greater likelihood of pleural effusions. Myocarditis and a rapid pulse due to constant toxic absorption are not contra-indications, but a failing heart is. All these things have to be ascertained before we can decide as to whether the opposite lung is sufficiently clear, or not too extensively involved by active tuberculosis or fibrosis to justify pneumothorax or thoracoplasty on the more extensively affected side.

We have to consider extensiveness of the disease (1) as it affects pneumothorax; (2) as it affects thoracoplasty.

(1) *Extensiveness of the Disease on the Opposite Side when Complete Collapse of the One Lung by Pneumothorax is Contemplated.*—Certain general principles only can be given, as it is extremely difficult to define in words the exact maximum amount of disease in the opposite lung which can be allowed; this is influenced by the whole general summary of the case one forms in one's own mind. Activity in the opposite lung is not a bar, but it must not be acute. Fibrosis may be present, but it must be localised. Scattered foci of infection throughout the lobes, the presence of

a cavity or of definite bronchiectatic changes are contra-indications. There must be at least two-thirds of healthy lung tissue. Reference must be made here to bilateral pneumothorax. In these cases not more than two-fifths of either lung is collapsed. The danger in these cases is heart failure. Bilateral pneumothorax is sometimes undertaken for bilateral disease, the collapse on the second side being started soon after that on the first. I am not much in favour of this, but I have undertaken partial bilateral collapse, beginning the treatment on the second side some six months after the first. In none of these cases was the bilateral pneumothorax conceived at the onset. Rather the second side has been started because treatment of the original side had not succeeded in arresting the progress of the disease in the other, but had been successful in arresting the disease in the collapsed lung.

(2) *Extensiveness of the Disease in the Opposite Lung as it affects Thoracoplasty.*—As a general rule it may be said that a much higher standard of soundness must be considered as essential. Some continental surgeons do thoracoplasty even when there are signs of activity in the opposite lung. Personally, I prefer that the lung which is called on suddenly to take on all the functions of respiration and oxygenation of the blood shall be free from signs of activity at the time of the operation.

I would urge that it is impossible to diagnose suitability on clinical evidence alone. The decision should be arrived at only after consideration of the general condition, the clinical and radiographical evidence of the extent and acuteness of the disease, a knowledge of the state and functioning capacity of the cardio-vascular system, of the degree of intestinal stasis, and of the state and functioning of all the other organs in the body, and of the mental temperament.

Finally, I would remind you of the brilliance of the results of surgical treatment. Of the cases in which a complete pneumothorax has been obtained without there being any adhesions, over 70 per cent. become fit to return to work; this high percentage is reduced to between 11 and 12 when adhesions interfere seriously or completely with the production of the pneumothorax. Of the patients on whom a thoracoplasty has been done, from 50 to 60 per cent. are "relatively cured," are free of symptoms, or much improved. The mortality of this operation is just over 8 per cent. (Gravesen, 8·6 per cent.; Jacobæus and Hey, 8 per cent.; Morriston Davies, 8·3 per cent.). The resulting deformity is surprisingly slight and is easily concealed by ordinary dress.

THE SPORE-FORMING BACTERIUM ON RICE-GRAINS

USED BY FAMILIES SUFFERING FROM BERI-BERI AND EPIDEMIC DROPSY.

BY S. R. BOSE, D.Sc., F.L.S.,
PROFESSOR OF BOTANY, CARMICHAEL MEDICAL COLLEGE, CALCUTTA.

SAMPLES of rice-grains used by families suffering from beri-beri and epidemic dropsy in different localities—viz., Howrah and Prome in Burmah—were kindly supplied to me by Major H. W. Acton, professor of pathology, Calcutta School of Tropical Medicine, for purposes of microtome section and appropriate staining.

Isolation of Bacterium.

During the investigation it was found that a spore-forming bacterium readily grew in cultures of "diseased" grains of rice (i.e., such grains as show a white streak inside when put in contact with water for two or three minutes) in agar medium, when the outer surface of the grain was sterilised by dipping in 95 per cent. alcohol for two or three minutes and washing in sterile distilled water for five to eight minutes, or by keeping in pure carbolic acid for five minutes, transferring to rectified spirit for 10–15 minutes until all traces of carbolic acid were removed, and finally, washing in sterile distilled-water tubes plugged with cotton-wool for 10–15 minutes; in both the methods followed the grains were carefully broken up with the help of a sterilised scalpel, and the broken pieces introduced into the agar media. Under similar conditions the same spore-forming bacterium was found in cultures from those grains of rice which did not show the white streak when put in contact with water. Subsequently it was found that the same bacterium ultimately grew on common market rice of Calcutta in agar media. This naturally aroused suspicion, and the slides containing the bacteria in question were sent to Mr. C. M. Hutchinson, Imperial Bacteriologist, Pusa Research Institute, for determination. He thought they were probably the spore-bearing forms of *B. subtilis*, a very common contaminating bacterium growing on the outer surfaces of fruits and seeds due to imperfect sterilisation.

Sterilisation.

They were proved to be so by adopting the following better method of sterilisation: The grains were dipped in 1/1000 corrosive sublimate and 95 per cent. alcohol for about three to four minutes, kept for two hours in sterile test-tubes of distilled water, poured out into a sterilised glass plate, and introduced into the agar media by means of sterilised forceps, some broken and others unbroken. The cultures were repeated on five successive days at the rate of four cultures a day. No growth was noticed in any tube. Subsequently, 95 per cent. alcohol was omitted altogether, and the rice-grains were dipped simply in 1/1000 corrosive sublimate for about three to four minutes; the subsequent steps were the same, and no tubes became infected though they were kept for weeks together. In case of broth cultures it was found that dipping of rice-grains in 1/1000 corrosive sublimate for six minutes was necessary to maintain the sterility of cultures. Anaerobic cultures were also tried in broth-paraffin media, and they also remained perfectly sterile.

Rice-grains from the stores of diseased families, and grains of common healthy rice, were boiled in water for an hour and a half and then put in agar tubes; in two days they gave rise to abundant growth of the same spore-forming bacterium, probably *B. subtilis*. If the grains were immersed in 1/1000 corrosive sublimate for four minutes before boiling in water for the same period, and agar tubes were inoculated with the grains, no growth was found in any tube. This showed that the spores are not destroyed by the ordinary method of cooking rice, and are ordinarily taken with rice diet without any harm.

The penetrating power of 1/1000 corrosive sublimate (watery as well as alcoholic) into the rice-grains was tested; it was found to have no penetrating power, and to be unable to enter into the rice-grains in any way. A control was kept of grains not dipped in corrosive sublimate, and the internal parts of the grains looked just the same in both the cases.

Germination Test of Gram Seeds Dipped in Corrosive Sublimate.

To show that dipping of gram seeds in 1/1000 watery corrosive sublimate has no deleterious effect on the living cells of the embryo within (1) dry gram seeds, (2) dry gram seeds soaked in water for about half an hour, and (3) water-soaked swollen gram seeds after being peeled off their skin, were dipped in 1/1000 corrosive sublimate for four minutes, separately washed thoroughly in water for more than an hour, and separately planted in earthen tubs, Nos. 1, 2, and 3. Germination into seedlings went on quite unhampered in all three tubs, and very soon normal and vigorous seedlings developed in all of them; growth was more especially marked in tub No. 3. This proved that dipping of gram seeds in 1/1000 corrosive sublimate has no deleterious effect on the living cells of the embryo within.

Time Required for Killing the Spores with Corrosive Sublimate.

A loopful of broth culture of this spore-forming bacterium was dipped in 1/1000 corrosive sublimate in a test-tube, out of which a loop was taken at intervals of six minutes, ten minutes, and 20 minutes, and these were put separately in large volumes of broth media in big flasks. These media, tested after three days, showed no growth, indicating that the spores were killed.

Inoculation of Healthy Rice.

Market rice-grains autoclaved in a big petri dish were inoculated with saline emulsion of the spore-forming bacterium from fresh agar slant. The dish was kept in a glass vessel containing water at its base under the cover of a bell-glass to maintain the humid atmosphere. In course of three days the grains became heavily infected, and looked soft and cloudy all over, instead of showing one single white streak inside. When such grains were dipped in watery corrosive sublimate 1/1000 for four minutes, and washed in sterile distilled water as before, and were introduced broken with the help of a sterilised scalpel into the agar media, all the media remained perfectly sterile. But if these grains, after being dipped in 95 per cent. alcohol for two or three minutes, and washed in sterile distilled water, were introduced, aseptically broken, into the agar media, all of the tubes showed growth of the same spore-forming bacterium. Also, if the grains were boiled in water for an hour and a half and then put into agar tubes, all of them showed abundant growth of the same spore-forming bacterium. Such inoculated grains were fixed in cellulose acetate in acetic acid, imbedded in paraffin, and were sectioned in microtome 4 to 6 μ, sections were nicely stained with Gram's iodine, none of the slides showed the presence of a single bacterium inside. These spore-forming bacteria were found to be proteolytic by inoculating solid egg media with them, and watching the liquefaction of the solid media in course of four or five days, the sporing bacteria themselves thriving in such media.

Conclusions.

So it is likely that this spore-forming bacterium, referred to as proteolytic, as well as the fungi (Rhizopus, Aspergillus, and a Mucor), mentioned in an editorial article in the *Indian Medical Gazette*, October, 1922, under the heading Epidemic Dropsy of Bengal—A Problem Solved, are only external contaminators. Their presence in the culture-media might be due to incomplete sterilisation of the outer surfaces of rice-grains as well as of almost all other fruits and seeds. Rice-grains in gunny bags are invariably stored almost in every house and shop in more or less damp, partially dark, ground-floor rooms and store-houses, where the temperature and humidity are usually high during the rainy season; a large number of grains damaged by boring insects are frequently found with healthy unbroken grains, and very few people take care to separate one sort from the other.

Under these circumstances it is inconceivable how, the organism being the same (the same spore-forming bacterium being present on the outer surfaces of both healthy and diseased rice), the conditions of development being the same—viz., high range of humidity and temperature—and the substratum on which the organism develops being the same (damaged grains being almost always present in a collection of healthy grains however small), it can in some grains succeed, and in others completely fail, in producing bodies (? amines) giving rise to epidemic dropsy. So long as no special conditions are made out, we must discredit this chance production of amines as a cause of epidemic dropsy.

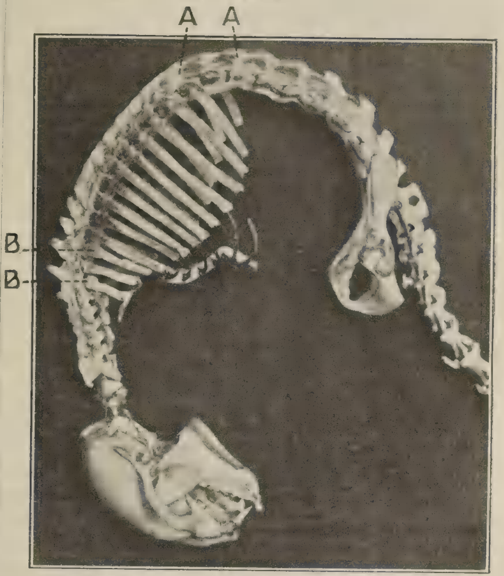
My thanks are due to Dr. Charu Chander Bose, Professor of Pathology of the Carmichael Medical College, for many valuable suggestions in the course of my work and for kindly going through the entire manuscript with me.

A CASE OF SPONDYLITIS DEFORMANS IN A KINKAJOU.

BY N. S. LUCAS, M.B., CH.B. OXF.,
PATHOLOGIST TO THE ZOOLOGICAL SOCIETY OF LONDON.

Spondylitis deformans is by no means common in man, and is apparently almost unheard of in the lower animals. There is a case recorded by Backmund as having occurred in the horse, but it has not been possible to verify the reference.[1] The kinkajou (*Potos caudivolvulus*), hab. Brazil, is one of the Arctoids—that is to say, it is placed between the coatis and the racoons. It is therefore closely related to the bears. Although strictly speaking a carnivore, it is actually a vegetarian, subsisting chiefly on fruit. It obtains the name of "caudivolvulus" from its powerfully prehensile tail. It is nocturnal in its habits. The history of the case throws no light on the origin of the disease.

FIG. 1.



General aspect of the deformity. A, Ossified interspinous ligament. B, Foramen unaffected.

The animal, a female, had been at the Zoological Gardens from 1917 to the end of 1923. The previous owner had kept it for over a year. It had been bent and rigid all the time. When walking it had the appearance of an inverted U, the knees and elbows being kept extended. The flexed position of the spine caused the head to be approximated to the abdomen with the snout pointing straight downwards. The prehensile power of the tail was fully maintained. It was decided that it was necessary to destroy the animal, but previously to this it was X rayed by Dr. W. L. Salmond, hon. radiologist to the Zoological Society.

The radiograph showed well the calcification of the anterior common ligament, especially in the lumbar region, and a gap opposite the juncture of the thirteenth and fourteenth dorsal vertebræ, which was subsequently verified in the skeleton. Unfortunately the cervical vertebræ were obscured by the assistant's hand holding the animal, but the importance of the X ray lay in the fact that the knee, ankle, elbow, and wrist were all shown as healthy, as were the metatarsals.

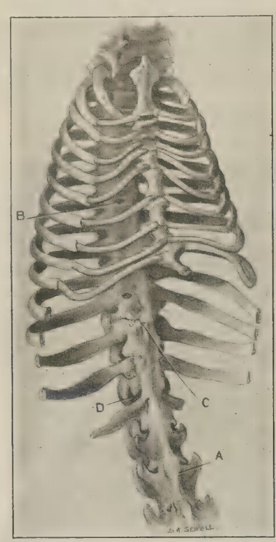
The animal was killed and a post-mortem examination of the viscera showed no abnormality in them. The body was fat and the coat in good condition. The hip- and shoulder-joints were dissected and found to be healthy. The body was then macerated, and the skull, vertebral column, pelvis, and the proximal half of the tail mounted as in Fig. 1, showing the general posture. The skull and atlas vertebra separated during maceration, and some of the teeth, which had been previously noted to be healthy, were lost. The rest remained intact.

---

[1] Deutsche tierärztliche Wochenschrift (Hanover), 1910, 486.

A close examination of the bones showed that the skull and the caudal vertebræ, except the first three, were healthy; these parts were white and smooth, while the rest was a dirty grey, with rough surface. The pelvis was grey. The teeth were healthy except the left lower canine and the bicuspid posterior to it, which were black and worn, but apparently had only recently become so.

FIG. 2.



Drawing of anterior view. A, Anterior common ligament calcified. B, Gap in its calcification. C, Incomplete calcification. D, Foramen not affected.

With regard to the vertebræ, the atlas was free and the axis nearly so. The remaining cervical vertebræ were joined by ossified inter-transverse and inter-spinous ligaments. The inter-vertebral discs are small but distinct between vertebræ 2, 3, and 4. The lower ones are less distinct owing to ossification of the anterior common ligament. Between the first four thoracic vertebræ the inter-transverse ligaments are ossified. Between the remaining 12 the inter-spinous and anterior common ligaments are also calcified completely, except for small gaps in the latter (see Fig. 2). The ossification between vertebræ 13 and 14 is not complete, bearing out the radiographic finding. The capsular ligaments of the ribs are all calcified. The lumbar vertebræ are all ankylosed except the last. The articulation between this and the sacrum appears normal. The inter-spinous ligaments of the first two caudal vertebræ are calcified. The cartilages of the hip-joints and the head of the femur appeared normal, but there was early ossification of the capsular ligament, as shown by bony outgrowths round the site of its origin. The deformity of the sternum was well marked and is of postural origin.

In attempting to put this case into one of the recognised groups the difficulty is encountered of the ignorance of early history and symptoms. It is not an ordinary rheumatoid arthritis, as the absence of disease from the cartilages and the freedom of the peripheral joints from disease are not in line with this type. The next group, von Bechterew's, "la kyphose hérédo-traumatique," is also unlikely, as the lesions in this group are chiefly in the cervical and upper dorsal vertebræ. In the specimen the lower thoracic and lumbar vertebræ are most affected. Further, it is unlikely that the animal would have survived the meningitis which accompanies this form; also there were no signs of nervous lesions, and the spinal foramina are not narrowed. Therefore the Strumpell-Marie type, "spondo-rhizomelique," with the chief site of the lesion in the lumbar vertebræ, is the most suitable group in which to place it.

The origin of the disease in any case is obscure, even in man. Here, at all events, gonorrhœa and syphilis can be ruled out. Heredity also is very improbable, since no animal with even a slight degree of this disease would be likely to survive in the wild state long enough to propagate its species. On the whole, therefore, an injury either just previous to or at capture is the most probable factor of origin.

UNUSUAL CUTANEOUS METASTASES IN CARCINOMA OF THE BREAST.

BY W. D. NEWCOMB, M.B. CAMB.,
ASSISTANT PATHOLOGIST, ST. MARY'S HOSPITAL, LONDON, W.

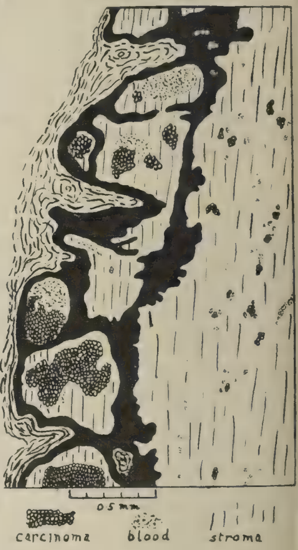
THE following case is of some interest from both the diagnostic and pathological points of view.

A woman, aged 73, was admitted to hospital in January, 1924, with a history of having had a blow on the left breast five years previously. In July, 1923, she noticed that the breast on that side was shrunken and discoloured. This discoloration spread over the whole chest wall in two or three months.

Condition on Admission to Hospital.—In the left breast was a hard lump about 3 inches in diameter, with an ulcer 1 inch in diameter in the centre. The crater of the ulcer was where the nipple had been. Multiple dark nodules, varying in size from 0·3 to 4 c.m. diameter, were seen over the whole of the chest; most of these were raised above the skin, while near the right breast were several larger warty growths. The left arm was swollen and painful, and a mass of glands was felt in the left axilla. The pigmentation of the cutaneous nodules was so noticeable that the condition was diagnosed as melanotic sarcoma by the surgeon in charge of the case. She died on Feb. 1st.

Post-mortem Examination.—This was performed on the day the patient died. The condition externally was practically the same as on admission. The mass of glands in the left axilla was found to have involved the axillary vein, which was thrombosed. Secondary growths were found in the left cervical and subclavicular lymphatic glands and in the liver. None of these growths was pigmented. On examining the skin carefully, it was noticed that while many of the nodules were deep purple, others showed a range of colours from lighter purple to pale pink. On cutting across a few of them it was obvious from the oozing that the colour was due to blood and not to a melanin pigment.

Microscopically the primary growth is a carcinoma simplex of the breast, consisting of rather large polygonal cells arranged in solid alveoli and trabeculæ. The skin nodules are more interesting. The larger ones show a papillomatous overgrowth of squamous epithelium lying on a core of secondary carcinoma. In some places the carcinoma appears to have formed small cysts in the epidermis itself, many of these cysts containing blood as well as growth. Serial sections show that they are not true cysts, but that the carcinoma has grown along lymphatics up to the surface epithelium and has then mushroomed out. At the same time the epithelium has grown even more rapidly, and the space between it and the carcinoma is filled with blood.



Many of the most deeply pigmented areas are but slightly raised above the surface. These show little proliferation of the squamous epithelium, but the carcinoma is growing in dilated capillary spaces. These spaces again are much too large for the small nodules of carcinoma growing in them, so that in many sections they appear simply as dilated capillaries filled with blood. In fact, the picture reminds one of a cavernous hæmangioma. It can be shown, however, that carcinoma cells are growing into all these blood spaces. In other areas numerous newly formed capillaries can be seen near small groups of carcinoma cells. This formation of new capillaries is quite abnormal, and is a prominent feature of some of the sections.

The accompanying semi-diagrammatic figure shows the proliferation and hyperkeratinisation of the surface epithelium which is drawn dead black. Masses of carcinoma can be seen apparently growing in cysts in this epithelium, and two of these cysts contain blood. In the dermis several small groups of carcinoma cells are shown with many new-formed capillaries near them.

Two features stand out in this case: (1) The proliferation of the squamous epithelium over the carcinoma instead of the usual ulceration. I have not seen this before, nor have I been able to find a description of it. Erichsen[1] describes a brownish discoloration of the skin, with the formation of desquamating crusts resembling the bark of a tree. This, however, would not appear a suitable description of this case. (2) The proliferation of vascular endothelium. Although it has not been possible to demonstrate any heaping up of endothelium, the formation of new small capillaries and of large dilated blood spaces must mean, at any rate, slight endothelial proliferation.

Drew[2] has shown the presence of a growth stimulating substance in carcinomata, and it is well known that sometimes the inoculation of a mouse with mouse carcinoma stimulates the stroma to produce a sarcomatous type of growth. It is possible that this is one of the rare cases in man where a similar condition has occurred. The carcinoma has caused a hyperplasia of both the squamous epithelium and the vascular endothelium.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF PSYCHIATRY.

THE LAW REGARDING CRIMINAL RESPONSIBILITY OF THE INSANE.

AT a meeting of this section on May 13th, under the presidency of Dr. T. B. HYSLOP, the subject set down for discussion was the proposed changes in the law regarding criminal responsibility of the insane.

Mr. DONALD CARSWELL opened with a presentation of the legal aspect of the question. He said the rules in the famous McNaghten case expressed the present law of England on this matter, and that there were only two points touching the credit of the McNaghten rules. The first was that those rules were unique in English law in that they had acquired the force of law without previous Parliamentary enactments or judicial decisions; they were merely the opinions of 14 out of 15 common law judges on certain questions framed for them by the House of Lords in 1843. He thought it was questionable whether those judges expected that their opinions would pass into English law. Neither had the rules been argued before the Court of Criminal Appeal. That court had not affirmed them on their merits. The second point was that it remained for the late Dr. Charles Mercier to show that the questions framed by the House of Lords were not those which in fact the judges answered; they substituted questions which they were able to answer.

The question being discussed at the present time, he said, was whether those rules should continue to have the force of law. Many were not satisfied that the rules ensured or secured certainty. It was said that without some more or less arbitrary guide, such as the McNaghten rules, there was likely to be a hopeless muddle. The alienist truly said that insanity was a relative term, and he only regarded his general experience of mankind; it was not enough for him that, relative to that experience, the patient who was suffering from general paralysis of the insane required a lunacy certificate. How could one define the criminal responsibility of the insane without inquiring into the whole concept of responsibility in general? Why should a mere statement of criminal responsibility involve a roving commission over the field of ethics? Punishment was given in accordance with the ethical standards prevailing at the time; there was no eternal and absolute standard. The great question to be answered was, did the McNaghten rules, according to our standards, do justice to insane persons who were charged with crime? If not, how was such justice to be secured? Mercier defined responsibility as that which was rightly liable to punishment, explaining that he meant by that, liable to punishment on grounds which appeared fairly just to the ordinary man when they were explained to him, and which commended themselves as equitable and right to the common man of this time and country.

Mr. Carswell went on to speak of the Memorandum submitted last year to Lord Justice Atkin's Committee on the subject by the Medico-Psychological Association, which the speaker considered not only of great interest, but also of permanent value. It was not accepted and acted upon, but he could claim it had not been answered. The conclusion of that document could be briefly stated as follows: No man should be liable to punishment for a criminal act committed during and by reason of insanity, and if it be proved that the act was committed during insanity, there was a presumption—which it was for the prosecution to establish—that it was committed by reason of the insanity. In other words, the jury must be instructed that they must not convict unless the prosecution had satisfied them that the insanity had nothing to do with the crime. The Atkin Committee asked how juries could be got to convict if this proposal were adopted. Mr. Carswell said he agreed with the Medico-Psychological Association's Memorandum, though he was in a minority amongst lawyers. He regarded the McNaghten rules, and all rules on the same model, as bad and useless anomalies, and calculated to defeat the ends of justice. The doctrine of irresistible impulse had achieved a larger measure of agreement between lawyers than had anything else, their agreement being that it was meaningless and impracticable, and that the sooner it passed into the limbo of vain imaginings the better. A great point about such impulsive states as epileptic insanity and puerperal mania was, not that the obsessions constituted irresistible impulses, but impulses resistible which had not been resisted. Such states did not carry immunity from punishment, but were just those in which a deterrent had the desired effect, as in the case of the soldier at the front tempted to run away, but the knowledge that he would be shot if he did kept him to duty.

The following point, he considered, ought to be put to the jury in such cases: Are you satisfied on a fair review of the evidence that the prisoner's act proceeded from a diseased mind? If so, you will acquit him; but if you think his act proceeded from pure wickedness of mind, you will find him guilty.

Discussion.

Dr. R. H. COLE said Lord Justice Atkin's Committee was to some extent hampered by having two separate medical reports, one from the British Medical Association as well as from the Medico-Psychological Association. In 1896 the feeling against the McNaghten rules was very strong, and the committee of that date set to work fully intending to advise that they be abrogated. But after giving a good deal of consideration to the matter they decided the rules could not be improved upon. Dr. Maudsley was the first medical man to attack those rules, and Maudsley's point was that at the back of the ordinary faculties of mind were the instinctive and emotional activities, which were largely responsible for criminal acts. If any attempt was to be made to tinker with the McNaghten rules, the speaker suggested that the question of defective reasoning should be left out, restricting the question to one of actual disease of the mind. He personally agreed that the rules should be abolished, and though eventual justice was done to the prisoner, he thought much injustice had been done to insane persons who committed criminal acts in the performance of the ritual attaching to a condemned prisoner on the capital charge, the judge meantime well knowing the ultimate goal was Broadmoor Criminal Lunatic Asylum. The Court of Criminal Appeal did much to undo the errors of juries, for the latter frequently gave little or no weight to medical evidence. In many cases the McNaghten rules hampered the medical man in giving his answers to questions. Logic required that degrees of insanity should be recognised, and that in minor degrees of that malady the person was not altogether irresponsible. The law must draw a hard-and-fast line, but the medical man could not say exactly where health ended and disease began. Doctors were not agreed on the subject of irresistible impulse, but it would help to have it included in the law of the land; the judges would see that it was not abused, and they were now more learned in medico-psychological matters than in times past.

---

[1] Erichsen: Science and Art of Surgery.

[2] Drew: Brit. Jour. Exp. Path., vol. iv., p. 51.

Mr. A. H. TREVOR (Commissioner, Board of Control) expressed his agreement with practically everything Mr. Carswell had said. The first question which should be asked was: Did the man know right from wrong? If he did, did he know the nature and quality of his act? Many people who were insane committed crimes well knowing the nature and quality of their act, and who, moreover, showed they were capable of much forethought and cunning in planning and carrying them out. With regard to uncontrollable impulse, if the tests proposed were not complete, they should be done away with. He, the speaker, believed that as soon as a person was proved to be the subject of genuine mental disorder the whole question of responsibility went by the board. He did not desire to see any alteration in the Criminal Lunatics Act, 1884: that should be taken with the Trial of Lunatics Act, 1883. Under the latter, the defence which had to be proved was, that the person concerned was insane so as not to be responsible, not that he was so insane as to be irresponsible. He, and those who thought with him, considered that it was a blot on the law of England that the kind of thing brought about by the McNaghten rules should be permitted to continue.

Dr. J. CARSWELL (Commissioner, Scottish Board of Control) confined his remarks to two points. The first was that the claim made before Lord Justice Atkin's Committee by the Medico-Psychological Association, based, as he contended, upon the considered judgment of those best entitled to speak on the matter, amounted to this: that the fact of insanity should be put to the jury. In two cases certainly this was not done; the question put to the jury was, Was the person insane so as not to be responsible in law? He did not think Lord Darling's Bill would settle this controversy, nor, indeed, would any other measure on similar lines.

The PRESIDENT said that insanity was incapable of definition, so also was sanity; attempts to define one or the other revealed a narrow comprehension as the terms were indefinable, hence there could be no line of demarcation between the two. The same held good with regard to responsibility. Until a definition of responsibility was agreed upon it could not be said what irresponsibility consisted of. Unfortunately, the questions of insanity and responsibility were intermingled. Doctors were questioned in courts of law as to sanity or insanity, but they were not allowed to express any opinion as to responsibility, yet in that lay the crux of the question. Learned judges, in charging the jury, held that it was for them, the jury, to deal with the question of responsibility. All who had had experience of the courts would recognise that as the truth. With regard to the McNaghten ruling, one had often encountered cases in which this ruling had been applied to the criminal who did not come within its provisions at all, and the criminal, having been found guilty, suffered the extreme penalty of the law. He asked what the McNaghten ruling had to say about somnambulism, the dream-state, epileptic automatism, and various types of epilepsy, and replied that it had nothing whatever to say about them. It was pathetic to sit in court and hear a jury being charged to apply rules which had no bearing whatever on the case; it was quite a frequent occurrence. This early Victorian ruling of 1843 was applied indiscriminately to all and sundry. The ruling should be banished from the courts, and every case treated on its merits, medical witnesses being allowed to give evidence on responsibility, not on insanity alone. This subject could not be dealt with conclusively until Harley Street was recognised on the question of responsibility.

Mr. CARSWELL, in acknowledging a vote of thanks for his paper, referred to a case which occurred 20 years ago, involving an obvious miscarriage of justice from the application of the McNaghten rules. He felt very strongly that these rules ought to be done away.

TUBERCULOSIS SOCIETY OF GREAT BRITAIN.

A MEETING of this Society was held at the Margaret-street Hospital for Consumption on May 16th, Dr. ERNEST WARD, the President, being in the chair.

Mr. FRANK KIDD read a paper on

Tuberculosis of the Urino-genital Tract.

Tuberculous lesions occurred especially commonly in young, ill-nourished adults, at a time when sex life is very active. These lesions could be confined to the urino-genital tract, in which case the prognosis was better than if the patients had lesions elsewhere. Mr. Kidd confessed to a clinical impression, which he had not yet confirmed by laboratory tests, that the more chronic cases were infected by the bovine strain, and the more acute by the human strain. The disease often remained unilateral for a long time, and often when both kidney and testicle were infected the lesions were on the same side. Cases with tuberculosis of the kidney were often nursed too long before they were taken to the surgeon, because medical men throughout the country were not familiar with the cardinal symptoms. The presence of both pus and tubercle bacilli in the urine made diagnosis certain, but cases should be diagnosed long before these symptoms manifested themselves. Most cases at the onset showed frequency of micturition and pain, localised at the neck of the bladder, at the end of micturition. Wasting, anæmia, and fever were generally absent. It was difficult to find tubercle bacilli in the urine, and this should be injected into a guinea-pig in suspicious cases. Pain in the kidney was usually absent for a long period, and often if pain were felt it was the healthy kidney that ached; but this was a late sign. Renal colic was uncommon. Sudden hæmaturia might occur. The general condition of the patient was good at first, and pyrexia was absent, unless there were a secondary infection. As to the physical signs, it was hard to feel any enlargement of the kidney in the early stage; again, the larger kidney might well be the healthy one. An expert could feel a thickened ureter per rectum or per vaginam, but this was not easy for the inexperienced. In males tuberculous nodules might be found in the prostate or testicle. In these cases, unless the urine was quite clear of pus, cystoscopy should be done at once. The presence of pus as well as of tubercle bacilli was of importance, since the tubercle bacillus might be filtered out through healthy kidneys. If the patient had pyuria it was necessary to get a specimen for examination, and the problem arose whether a catheter specimen was required. Nowadays the smegma bacillus could easily be distinguished morphologically by pathologists from the tubercle bacillus, and owing to the danger of setting up a secondary infection Mr. Kidd did not advocate passing a catheter in males. A much safer method was to use an ordinary irrigator with a urethral nozzle to wash out the urethra, and then to get the patient to pass urine into two glasses, using the second glass for examination. In females the catheter had to be passed, but the precaution should be taken to inject a weak antiseptic—for example, oxycyanide of mercury, 1 in 4000—before the catheter was withdrawn. In 30 per cent. of cases with renal tuberculosis pathologists were able to find bacilli. On the other hand, an expert could diagnose 90 per cent. or 95 per cent. of cases by means of a cystoscope, and this was the most certain method of diagnosis. When tuberculous infection was regarded as certain both ureters had to be catheterised. There was usually pus coming from one side to incriminate the kidney on that side. Functional tests should always be done. Mr. Kidd preferred the indigo test to urea-concentration tests, since he regarded it as dangerous to leave catheters in situ over a long period. Blood-urea was not a very useful test, since in his experience a positive result was only obtained in late inoperable cases, not in early operative ones. X rays were useful to confirm cystoscopic and pathological findings. Some patients were almost impossible to cystoscope, even with spinal anæsthesia, which was the most useful method in late cases with ulcerated and very sensitive bladders. When cystoscopy was not possible it was Mr. Kidd's practice to make a small incision of one inch in the middle line and to feel the ureters. If one were thickened the corresponding kidney was regarded as the infected one, and the patient had to run the risk of its removal. Differential diagnosis was mainly from *B. coli* infections. These were characterised by remissions and by high fever during attacks. Stone could be excluded by X rays. Patients with tuberculosis in other parts of the body should always be watched for frequency and pus in the urine. Spontaneous cure of renal tuberculosis was unknown, although some cases might live for 20 years or more. Apparent cures were not uncommon, and were due to the fact that individual lesions in the ureter may heal, and the ureter may become fibrosed and closed up completely from time to time; but if the case was carefully watched it would be found that infected urine bursts through again after a certain time. The operative mortality nowadays in the hands of competent surgeons was not more than 2 per cent.; in the 65 cases operated on since 1912 on which Mr. Kidd had founded his remarks that evening there had been no deaths. Thirty-eight had been followed up and were cured. Of these 28 had been traced quite recently, and had lived in good health for periods varying between 1 and 14 years. Nine cases were very much improved, eight were apparently cured, but had not recently been seen, ten were dead. In many of these cases the wound had healed by first intention, special operative methods to avoid infecting the wound having been taken. After-treatment was important. If the patients went back to work too early, or if they were not given adequate and suitable food, the mortality rose. Comparisons of results of surgical and medical treatment in these cases showed that results were much better with surgery. Wildbolz, of Berne, who had published a large series of cases with very good results, estimated that three-fifths of his cases became completely well, but that if the patient was not well in three years the chance of ultimate recovery were poor. Mr. Kidd quoted instances of women who had had a tuberculous kidney removed, and got through a subsequent pregnancy without harm.

Tuberculosis in the Testicle.

When both the kidney and the testicle were affected it was well to remove the kidney, since the testicle often cleared up, but when the testicle alone was infected Mr. Kidd was inclined to temporise, since these lesions often healed up quite well on tuberculin, or at least became quiescent. He only advised removal if (1) there was a kidney lesion also, (2) if tuberculin failed to act, (3) sometimes in bilateral tubercle if there was pain. He had no doubt himself that tuberculin had a specific action on tuberculosis of the ureter and testicle and especially on the bladder. It was even dangerous to give tuberculin to bilateral kidney cases, since the ureteric lesion might heal and become fibrosed so as to block up the lumen. He found Koch's new T.R. the most useful, and urged that too big doses should not be given; 1/100,000 up to 1/5000 mg. should be administered and never more than 1/5000. He had tried Dreyer's vaccine on one very early case with no success. He had had some success with artificial sunlight and with real sunlight in cases sent to Rollier at Leysin. As to preventive measures, he advised patients who had once been infected to drink only cooked milk and to keep away from acquaintances with tuberculosis; also not to go back to work too soon, and not to work too hard.

Discussion.

The PRESIDENT thanked Mr. Kidd for his masterly summary of a difficult subject. He said that tuberculosis of the lung was more common in France than in England. He wondered whether tuberculosis of the genito-urinary tract was also more common. He had understood that Dr. J. H. Sequeira and Dr. Louis Cobbett, working in different fields, both held that it was impossible to distinguish clinically bovine and human bacilli. He asked Mr. Kidd to explain what was the lesion seen in cystoscopy which enabled experts to diagnose tuberculosis of the bladder or urethral orifices so quickly. Was it a retracted ureter, and did not this sign also occur in *B. coli* infections? Dr. Ward had tried Dreyer's vaccine in two cases with no benefit to the patients.

Dr. T. Y. PEYTON asked whether Mr. Kidd meant to suggest that tuberculosis in the genito-urinary tract was primary? Since such wonderful results appeared to be obtained by surgery in genito-urinary tuberculosis, was it not possible that the present tendency was to concentrate too much on the constitutional element in the treatment of other forms of tuberculosis? He asked whether bacillæmia was often found after operation.

Dr. H. A. ELLIS had not been successful in differentiating bovine from human infection by clinical differences. He suggested that if Mr. Kidd sent the infected kidneys after removal to Mr. Stanley Griffiths, he would probably be glad to isolate the strain, and confirm or disprove the clinical diagnosis.

In reply, Mr. KIDD said that bacillæmia used to be not uncommon after operation, but nowadays it was customary to cauterise the end of the ureter, and also to take out a large quantity of fat with the kidney so as to avoid disseminating the infection. He could not give a picture of the bladder condition which suggested tuberculosis to the expert, but there was no doubt that it was easily recognised with practice.

THE LATE DR. W. SCOWCROFT, OF CHEADLE ROYAL. On May 17th, at the age of 70, Dr. Walter Scowcroft, of Cheadle, passed away at his residence, St. Ann's Cottage, Cheadle. After completing his academic career at Owens College Medical School, Dr. Scowcroft qualified as M.R.C.S. in 1879, and ten years later as L.R.C.P.I. He was a house surgeon in the Royal Infirmary, Manchester, and for some years assistant medical officer in the great lunatic asylum, known locally as "Cheadle Royal," of which, on the retirement of the late Dr. Mould, he became medical superintendent, an office he resigned a few years ago. Many old medical students at the University of Manchester will retain a pleasant recollection of Dr. Scowcroft, of the knowledge he imparted to them as lecturer on mental diseases, of the journey by coach to and from Cheadle, and of Dr. Scowcroft's unfailing hospitality.

Reviews and Notices of Books.

History of the Great War.

Medical Services, General History. Vol. III. By Maj.-Gen. Sir W. G. Macpherson, K.C.M.G., C.B., LL.D. London: H.M. Stationery Office. 1924. Pp. 556 + viii. £1 1*s.*

Each volume of the medical history of the war, as one reads it, compels admiration for the skill and patience of the editor, who from the myriad threads of fact has woven so even and well-patterned a web of history. This volume deals with the evolution of medical organisation in the field. In the common conversation of the profession, medical organising power is usually given second place to advanced surgical or medical skill. Yet the ablest surgeon is no help to a man lying wounded five miles away in the middle of a muddy field, and it is the organiser who brings the patient quickly to the surgeon specialist whom he has already provided with a well-warmed and well-lighted operating theatre and all necessary equipment. The skilled surgeon saves men by dozens in the day; the skilful organiser may bring relief to thousands.

In this section of the History we learn how it was managed. The regimental stretcher-bearers go and find the wounded and bring them to the doctor at the regimental aid-post; whence the field ambulance-bearers take them to the main dressing stations, whence the motor ambulance convoys remove them to the casualty clearing-stations of the division, through which they reach the hospital trains. Only very precise and well-considered arrangements made in the Fourth Army before the battle could have relieved its casualty clearing-stations of 14,936 wounded on the third day of the battle of the Somme in 1916. Motor ambulances and other modern devices, indeed, made this possible, but all have behind them the devotion of the men who, in relays every 600 or 800 yards, sheltered perhaps as they waited by derelict tanks, carried the stretchers at the front. Knee-deep in mud they were on the Somme. And it was not only mud they met: as they carried the wounded across the Piave in 1918 they were waist-deep in the river. In Palestine at times the mud was so deep and universal that only camels, with their soft, spreading feet, could cope with it. In early 1918 in Palestine the troops were on half rations in the heavy rains, and two mounted divisions and a brigade, and 4000 horses besides, had to be sent back temporarily to the advanced base, as food could not be brought up for them.

The editor tells, and tells with special approval, of the clever scheme of the D.D.M. of the XXIst (the Western) Corps, Col. E. P. Sewell, to provide for the care of the sick and wounded in the great advance (p. 449). This advance became notable later for the sickness that developed. The Desert Mounted Corps, in six weeks, sent back of wounded only 300, but 11,300 sick. This sickness was at first due to malaria, arising as soon as the troops got away from their well-protected stations, but later to influenza.

Influenza is first mentioned in France and in Italy in May and June, 1918; cases were only slight but sufficiently numerous to disable a division and prevent an already planned attack (p. 259). It is next reported from Syria and Damascus in early October, and about the same time it recurred both in France and Italy, but this time seriously complicated with broncho-pneumonia. Medical officers of hospitals were, of course, trying all the time to make their patients more comfortable, but sometimes their zeal would seem to have almost been excessive. A casualty clearing-station is supposed to have 23 tons of equipment transportable in eight lorries. After a long stationary period, one of these, being ordered to move, had 100 lorries' load of stores, of which 10 were road metal.

In reviewing the first of these volumes in 1922 we noted that the only person against whom an error of judgment was alleged was a civilian. This volume is more judicial, though in certain cases omissions may occur in allotting the credit due. In such a work these things are inevitable, though it is clear that great care has been taken to avoid them. For example, Lieut.-Col. C. Garner, mentioned without emphasis on p. 381, was the Director of Public Health in Egypt, who worked with such energy and success in coping with the difficulties of embarkation at Gallipoli (p. 370). The Egyptian medical officers of the Egyptian Public Health Hospitals are stated to have given the greatest satisfaction by their work, "both as regards the comfort of the patients and results."

An interesting and well-printed book, with excellent maps.

Orations and Addresses.

By Sir John Bland-Sutton, Consulting Surgeon to the Middlesex Hospital. London: William Heinemann (Medical Books), Ltd. 1924. Pp. 161. 10*s.* 6*d.*

Sir John Bland-Sutton has done well to publish in book form twelve selected orations and addresses which he has delivered in divers places and has published in sundry journals; and, seeing what an interesting and charming volume has resulted, we are gratified to remember that we had the pleasure of putting before our readers several of the most important chapters with their apt and amusing illustrations. The place of honour in the volume is given to the Hunterian Oration of 1923, which will long be remembered by those who heard it as a masterly description both of the range of work of John Hunter, the patron-saint of surgery, and of his personality. Sir John Bland-Sutton has followed Hunter's labours in all details and has, further, gone over much of the actual ground where those labours were carried out; in fact, the second chapter of the book describes Hunter's investigations in Portugal, mainly into bird life and the phenomena of migration. The Hunterian Oration is an admirable supplement to many previous orations, because it reveals so clearly the manner of man that Hunter was. He is seen to have been a practical worker of limitless curiosity and a philosopher capable of the largest generalisations, while he was an untiring researcher and scrupulous in all details, knowing that the largest inferences may derive from the smallest facts. But he was not a literary man; he read few books and had no gift of exposition. It is perhaps for this reason that year after year Hunterian lectures prove valuable; they serve not only their pious object of keeping Hunter's fame alive, but they supply the reasons for that fame which Hunter's own written work often left in uncertainty.

The President of the Royal College of Surgeons of England is a disciple as well as an admirer of the great John Hunter, for, as will be seen in this multifarious collection of essays, his curiosity in respect of pathological manifestations knows no limits, and while he is an accurate and reverent chronicler of the exploits of the past, he is abundantly ready to recognise the value of the work of to-day and its promise for to-morrow. The range of the essays is very large, and every man who has some conception of what biology means will find in them something informatory, challenging, or amusing.

Venereal Disease.

Its Prevention, Symptoms, and Treatment. Second edition. By Hugh Wansey Bayly, M.C., Hon. Sec., Society for the Prevention of Venereal Disease, &c. London: J. and A. Churchill. 1924. With 58 illustrations. Pp. 176. 7*s.* 6*d.*

This is the second edition of a well-known little handbook of which the first part deals with the prevention of venereal diseases, and the second with their description, symptoms, and treatment. The first is the more important, we presume, from the standpoint of the author, and puts forward his well-known views as to prevention by means of self-disinfection. The position in regard to self-disinfection and its results is, we imagine, now well recognised by medical men and many of the laity and legislators. Mr. Bayly has set it forth here clearly, concisely, convincingly

The second part of the book is well written, and can only be a synopsis, but within these limits it is excellent. The whole of the work is easily intelligible by people who are not specialists in venereal diseases, and should be read by them with profit. We must regret Mr. Bayly's reference to his legal controversy with Lord Astor arising out of matter connected with the author's election campaign at Plymouth.

SUNSHINE AND OPEN AIR.

By LEONARD HILL, M.B., F.R.S., Director, Department of Applied Physiology, National Institute of Medical Research. London: Edward Arnold and Co. 1924. Pp. 132. 10*s.* 6*d.*

A COMPENDIOUS study of the effects of sunshine and open air has long been needed and is specially welcome when it appears in comprehensive, concise, and readable shape. Dr. Hill begins with a few pages about that paradox of nature, the Alpine winter climate, which has the remarkable property of simultaneously scorching and freezing the body. These two factors, although unpleasant when acting independently, yield a resultant which has the rare quality of being both delightful and health-giving. Further considerations lead the writer to the conclusion that the least healthy surroundings are those which involve cold feet and warm humid air. These conditions are all too common in modern houses where cold draughts chill the feet while the head is surrounded by warm stagnant air. In these circumstances the nasal mucous membrane becomes boggy, congested, and covered with thick secretion. The Alpine climate provides the contrary condition; the air surrounding the head is cool, while the feet are on ground which is well warmed by the sun. The mucous membrane of the nose is pale, taut, and free from secretion, infection being guarded against by a free flow of lymph, which evaporates as soon as it reaches the surface. Dr. Hill considers the expression "catching a cold" to be misleading, and explains the popular belief that draughts are the cause of colds by the fact that during the initial period of the infection there is slight fever and consequently increased susceptibility to cold. He believes that the resistance of the lungs to disease is increased in a similar way by Alpine air, which causes increased evaporation from the respiratory membrane and consequently a greater flow of blood and lymph.

In the chapter on sunshine, Alpine and English climates are again contrasted, and it is found that the Swiss health resort Montana has about as many hours sun in winter as England has in summer, and that the intensity of sunlight, as measured by its capacity to heat black fur, is about the same in a Swiss December as it is in an English July. This difference is due to the greater clearness and dryness of the air at high altitudes; 75 per cent. of the sun's rays reach an altitude of 6000 feet, while only 50 per cent. reach sea-level, and in a smoky city the amount may be reduced to one-third or less.

With regard to the biological action of light, Dr. Hill has repeated Weissner's experiments, which appeared to show that infra-red rays possessed a bactericidal action quite apart from the heat they produced. The conclusion reached was that when the temperature of the bacteria was carefully controlled infra-red rays have no lethal effect. The ultra-violet rays are strongly bactericidal, but their penetrating power is so slight that this property cannot come into play even in the treatment of so superficial a lesion as lupus. Dr. Hill considers that the chief function of cutaneous pigment is to protect the body from ultra-violet rays. The red corpuscles of the blood also act as a screen and convert visible rays into heat. This reaction is believed by some to have considerable influence in the immunising power of the blood. Dr. Hill finally puts forward the theory that ultra-violet rays in damaging the surface cells of the skin stimulate the defensive mechanism of the body, white corpuscles and immunising substances being increased in order to deal with damaged cell products. The rate of metabolism depends to a large extent on the cooling power of the atmosphere, and this in its turn depends on the temperature and humidity of the air. A mist or fog feels cold, but its cooling power is low; on the other hand, the feeling of warmth and a high cooling power frequently accompany one another in the Alps in winter. The relative humidity of the air is not nearly so important for health and comfort as is the "physiological saturation deficit," which is the difference between the amount of water vapour in the air and the amount the air would contain if saturated at body temperature. Great increase in basal metabolism is characteristic of the open-air treatment of tuberculosis and is most beneficial to health. Dr. Hill emphasises the importance of wearing the lightest clothing that can be tolerated without shivering, as it must not be forgotten that however bracing the air its action will not be exercised through thick and impervious clothing.

This book is well worth reading, and although of particular interest to the medical profession, should be much more widely appreciated. Both medical and lay readers will find it full of interesting facts and permeated throughout with shrewd common-sense.

JOURNALS.

QUARTERLY JOURNAL OF EXPERIMENTAL PHYSIOLOGY. Edited by E. SHARPEY SCHAFER and Others. Vol. XIV., Nos. 1 and 2. London: Charles Griffin and Co., Ltd. 1924. Pp. 1–207. 20*s.*—The Effect of Pathological Sera on Plain Muscle, by Lena C. Adam.—Secretion by the Human Fœtal Kidney, by Evelyn E. Hewer. The time when the kidney first becomes functional is very obscure. By examining the kidneys of human fœtuses of different ages by means of differential staining processes, Miss Hewer concludes that the kidney in the human fœtus is certainly functioning as early as the twelfth week of development, and quite probably as early as the ninth week.—Animal Experiments on the Inhibition of Hæmolysis by Blood Serum, by Eric Ponder.—Measurement of the Diameters of Erythrocytes, by Eric Ponder and W. G. Millar. The authors describe in detail a method for the measurement of the red cells in the plasma of human blood, the cells being photographed under suitable optical conditions and measured from the negative. The error in measurement does not exceed $0{\cdot}2\mu$.—The Spindle-cells in Frog's Blood, by L. J. Notkin.—Correlation between Area and Hæmoglobin Content of the Erythrocyte, by Eric Ponder.—Measurement of Colour-blindness in Terms of Wave-lengths, by H. E. Roaf. As a result of an examination of 28 cases of colour-blindness, it was found that the defect is always in the red end of the spectrum. Edridge-Green has found cases of shortening of the violet end of the spectrum, but actual shortening of the spectrum may be due to a different kind of defect than failure to recognise colour. The cases differ in the degree to which they fail to recognise differences in the red end of the spectrum. Some correspond to a cutting off of the spectrum to about $\lambda 6200$, others require the spectrum to be cut off to about $\lambda 5800$, and others require a reduction to about $\lambda 4800$ before the diagram matches the one from which it was copied. The W-L $\lambda 5800$ and $\lambda 4800$ correspond approximately to those regions where the perceptible change in hue with W-L is most marked.—Sutherland Simpson contributes two papers on the effect of thyroidectomy on growth in the sheep and goat as indicated by body-weight and on the cutaneous system. The general conclusion is reached that loss of the thyroids and parathyroids is tolerated much better and for a longer period in herbivora such as the sheep, quietly grazing in a field, than in the more active carnivora such as the dog and fox. In the case of the parathyroids the difference may depend on the characters of the intestinal flora.—G. W. Scarth contributes two papers, one on Colloidal Changes Associated with Protoplasmic Contraction, and the other on the Action of Cations on the Contraction and Viscosity of Protoplasm in Spirogyra. The chloroplasts of spirogyra, normally a gel, may be stimulated to undergo contraction along their long axis. This contraction is reversible. The chloroplast during contraction becomes more plastic until frequently solation takes place. The chloroplast is doubly refractive, due to a regular arrangement of molecules. In several ways the behaviour of protoplasm under the action of cations resembles that of a physical colloid.—Effect of Insulin on the Respiratory Exchange of Normal Animals, by B. R. Dickson, J. J. R. Macleod, and others. The decided rise in the respiratory quotient (R.Q.) in normal animals that have been starved or kept on a protein-free diet that follows the ingestion of carbohydrates does not occur in completely depancreatised dogs provided a few days have been allowed to elapse since the operation. It also fails to occur under similar conditions in severe diabetes in man. The failure of the R.Q. to rise in diabetes, coupled with the fact that the ingested sugar reappears in the urine, indicates clearly that the organism has lost the power to oxidise carbohydrate. This is due to the absence of the internal secretion of the pancreas. When insulin is administered to the depancreatised animal or the diabetic patient the R.Q. behaves as in a normal animal. Insulin not only affects the R.Q., it also lowers the blood-sugar, both when the sugar is at a normal level and when it is greatly above it. These two effects are coupled in the diabetic animal with a third—namely, it restores to the animal the power to deposit glycogen in the liver. The relation between the blood-sugar level and the deposition of glycogen and the oxidation of sugar in normal animals, following the administration of insulin, requires investigation. The authors' observations were made on rabbits and dogs. The results of the administration of insulin were not exactly the same in dogs and rabbits; the authors tabulate and discuss their results. The evidence would seem to indicate that the sugar which disappears from the blood, as well as the glycogen which disappears from the store of this material in the tissues, becomes converted into some intermediate form of carbohydrate, which has no reducing power, and is, therefore, not included in the sugar estimations. It was also found that both the total CO_2-combining power and the total amount of CO_2 of the blood are not significantly lowered as a result of insulin.—T. Graham Brown contributes his twenty-eighth article to the physiology of the nervous system, entitled "Absence of Algebraic Equality between the Magnitudes of Central Excitation and Effective Central Inhibition given in the Reflex Centre of a Single Limb by the Same Reflex Stimulus." The author defines his terminology, and the methods employed of obtaining reflex and other movements in cats—decerebrate and low-spinal, and his deductions from the experimental results.—In a short note W. D. Halliburton and D. H. de Souza describe certain actions of pancreatic juice on milk.

Reports and Analytical Records.

BYNOGEN.

(ALLEN AND HANBURYS, LTD., 37, LOMBARD-STREET, E.C. 3.)

THIS is a concentrated casein-glycerophosphate food, with an approximate percentage composition of sodium glycerophosphate 2 per cent., calcium 2 per cent., magnesium 1 per cent., soluble milk proteins 75 per cent., and soluble extract of malt and whole wheat 20 per cent. The preparation is clearly a substantial food, its effects as a tonic food being enhanced by the presence of the organic phosphates, which are well known to help nutrition. Further, it showed a distinct digestive action on starch, and the test for active enzymes gave a well-marked response. Clinical experience has testified to the value of Bynogen in debilitated conditions generally, and those recovering from severe illnesses have benefited by its employment. A fine, cream-coloured powder, it can be sprinkled on food or prepared as a liquid beverage, the dose for an adult being two or three teaspoonfuls with or after each principal meal. For children half the quantity is sufficient.

ENERGEN BREAD.

(THERAPEUTIC FOODS CO., WILLESDEN, N.W. 10.)

The exclusion of bread from the dietary is the most irksome of all restrictions to which the diabetic patient may be subjected in the effort to reduce the intake of carbohydrates. For this reason many substitutes, more or less resembling it in texture and flavour, have been placed on the market. Those most extensively used are gluten bread and similar products prepared from gluten flour. The processes involved in the treatment of wheaten flour to separate the starch from gluten are laborious and expensive, and for this reason few of the so-called gluten flours are satisfactory from the standpoint of low starch content. Absolute prohibition of starch, however, is no longer regarded as essential in diabetic treatment, the patient being allowed a proportion of carbohydrates in addition to fat and proteins, in relation to his tolerance of the former. This being the case, we think that the manufacturer should state the percentage of carbohydrate in his product, since this practice would be of great assistance to the physician in prescribing a diet.

The Energen bread submitted to us for examination was in the form of rolls each weighing 34½ g. (1¼ oz.). When analysed the following results were obtained:—

Altered starch (carbohydrate) ..	45·0	per cent.
Protein	36·0	,, ,,
Moisture	9·5	,, ,,
Fat	5·7	,, ,,
Crude fibre	0·1	,, ,,
Undetermined	3·7	,, ,,

Ordinary white bread with a moisture of 36 per cent. contains about 53 per cent. of carbohydrates and 6–7 per cent. of protein, so that Energen is much lower in carbohydrates and higher in protein content. While it is true that no claim is made that Energen is free from starch, it is obvious that its use in cases of diabetes will require the supervision of the physician, and the patient should not be allowed to obtain the idea that it can be safely used in any quantities that appetite may suggest.

ATOQUINOL TABLETS AND OINTMENT.

(CIBA BRAND.)

(THE CLAYTON ANILINE COMPANY, LIMITED, 68½, UPPER THAMES-STREET, LONDON, E.C. 4.)

These preparations are put on the market through the English firm by the Pharmaceutical Department of the Society of Chemical Industry, Basle, and present an attempt to deal with uric acid by "getting it out of the system." Atoquinol or allyl-phenyl-cinchoninester has been used successfully with sodium bicarbonate and an increase in the amount of fluid consumed in cases where gouty symptoms were accompanied by urine loaded with uric acid, while the tablets of atoquinol have been of service in gouty urticaria. The tablets are supplied in tubes holding 20 tablets each containing 4 gr. of the drug, and the unguent in collapsible tubes at 20 per cent. strength.

ERRATUM.—An error and a misprint occur in the first line of the recently published report on Kalzana. This preparation was described as "identical with albulactin." The correct constitution was given immediately below, showing that Kalzana is a chemical combination between calcium lactate and sodium lactate. We regret the error which, we are informed, has created some confusion in our readers' minds.

THE LANCET.

LONDON: SATURDAY, MAY 24, 1924.

THE APPEAL IN THE HARNETT CASE.

The judgment in the appeal by Dr. C. H. Bond and Dr. G. H. Adam against the judgment entered by Mr. Justice Lush in the action brought against them by Mr. R. S. Harnett will have been welcomed by members of the medical profession with a sense of relief, and read by few with any surprise. The judgment, which was given by the Lords Justice Bankes, Warrington, and Scrutton, allowed the appeal of Dr. Adam against whom £20,000 damages were awarded jointly with Dr. Bond, and ordered judgment to be entered for him. Against Dr. Bond in addition to the joint damages, were awarded £5000, and their lordships ordered a new trial in his case, Dr. Bond to have the costs of the appeal, the costs of the first trial, while following the ultimate issue, to be limited to such as would have been incurred if the original claim had been against Dr. Bond alone, and only for the period between the plaintiff's alleged detention at the Commissioners' office and his return to Dr. Adam's care (see p. 1072). The new trial is conditional upon Mr. Harnett repaying the money already paid under the order of the Court below.

The result of the verdict and judgment in the Court below in the case of both defendants was contrary to the conclusions at which the ordinary citizen would have been able to arrive after the perusal of the evidence given in court, and it must have been felt by all that error had occurred in the administration and application of the law at a trial in which, no doubt, great sympathy was excited in the minds of the jury in favour of the plaintiff—for admittedly he had had bitter experiences. The generally important feature of the case, and the one which occupied the most prominent place in the judgment of the Court of Appeal, was the decision arrived at by the jury that Dr. Bond and Dr. Adam should be held jointly liable to pay £20,000 as damages to Mr. Harnett, in respect of his detention in a succession of mental homes from a date in December, 1912, to October, 1921. The alleged liability of Dr. Bond in this respect arose from his having detained Mr. Harnett at the offices of the Commissioners of Lunacy for a certain number of hours, thus bringing about the return of Mr. Harnett to the care of Dr. Adam at Malling Place. Admission on Dr. Bond's behalf that this action had no legal support under any provision for the care of the insane has rendered it necessary that there should be a fresh trial to determine the proper extent of Dr. Bond's liability, and this matter will be subject to the observations of the Court of Appeal as to the remoteness of the damage for which compensation had been awarded. When judgment was given for £20,000, it had been held by Mr. Justice Lush that the whole of the detention of Mr. Harnett over a period of nine years might be attributed to the action of Dr. Bond in causing the revocation of Mr. Harnett's leave of absence on probation from Malling Place, or else to the joint action of Dr. Bond and Dr. Adam in the same matter. No subsequent removal to any other place of treatment, no subsequent certification or other duty definitely imposed by the legislature, and performed by any doctor or official visitor up to almost the end of 1921, constituted a *novus casus interveniens* to break the chain of causation, and to relieve Dr. Bond and Dr. Adam from the consequences of what the jury found to be a wrong view entertained by them as to Mr. Harnett's mental condition on Dec. 14th, 1912. It may be suggested that to find Dr. Bond and Dr. Adam responsible for the whole of the nine years' detention of Mr. Harnett was to place both of them, but more particularly the former, in the position of a judge who sentences a prisoner to a term of penal servitude, and to allot to the medical officers of the mental institutions in which Mr. Harnett was afterwards confined, to the Commissioners and to their visitors no higher functions or powers than those of governors of prisons and visiting justices whose duty it is to keep convicts in custody and to see that they are properly treated. The jury at the trial were not asked to say what Dr. Bond's position would have been if, honestly believing that Mr. Harnett was not fit to be at large, he had sent him away, and if, through his happening to be in a worse mental condition than, in fact, he was on that afternoon in December, he had inflicted on others, or himself had suffered, some physical injury. As matters stand Dr. Bond has to face a fresh trial, knowing that a limit has been placed by the Court of Appeal to the liability arising out of his action. In the circumstances no further comment upon Dr. Bond's case is permissible. Dr. Adam, on the other hand, is to be congratulated warmly upon having obtained from the Court of Appeal a judgment which completely exonerates him from responsibility for such error as the jury attributed to him. The law relieves from liability in express terms a medical man who carries out duties such as his, using reasonable care in their performance. The jury found that when Dr. Adam sent a car to fetch Mr. Harnett back from Whitehall, he honestly believed that his late patient was not fit to be at large, but that in acting as he did he did not use reasonable care. It was urged at the trial that Dr. Adam ought to have gone personally to fetch his patient, but the Court of Appeal brushed this point aside as magnifying the importance of an insignificant detail.

The result of the judgment should be that medical men charged with the duty of treating the insane, or of sending them to be treated, if they comply in spirit and letter with the law regulating such matters, will be able to act with such confidence as they possessed prior to the trial before Mr. Justice Lush reached its unfortunate conclusion. They may and should be encouraged by a significant passage quoted by Lord Justice Bankes as coming from that wise and learned judge, Lord Lindley, who said in the course of a judgment dealing with the Lunacy Act of his day, that it had "given to justices of the peace and medical men wide powers, based upon the theory that they could be trusted."

◆

PYORRHŒA ALVEOLARIS.

The problem of dental sepsis is of importance alike to dentist and doctor, for since the work of Dr. William Hunter, the view that it is a common cause of general disease has taken a definite place in medicine. Now that the radiogram has revealed the frequent existence of apical rarefaction in pulpless teeth these lesions have somewhat overshadowed the significance of pyorrhœa as a cause of dental sepsis, and by implication, a cause of constitutional symptoms. Pathologically there does not seem to be any justification for this view. Clinical evidence would suggest that all forms of dental sepsis are a potential source of danger, though the fact that in many individuals gross dental sepsis may coexist with excellent health, suggests that the pathology of various dental lesions is imperfectly understood. From the standpoint of the dentist, pyorrhœa and dental caries are the two chief agencies concerned in the destruction of the teeth, and the treatment of the former disease plays a large part in every dental practice. A series of articles on pyorrhœa, which appears in the *Dental Surgeon* of May 10th, affords an opportunity of reviewing the present state of our knowledge of this disease. This knowledge is meagre. The host of theories put forward to account for the causation of pyorrhœa, and the different methods of treatment in vogue are a sufficient index of our ignorance. It is not definitely settled whether pyorrhœa is a local condition, or whether it is a local manifestation of some general disturbance. In this country many dentists hold the view that it is a local lesion, in accord with the views put forward with so much cogency by Mr. J. G. TURNER.[1] But Mr. F. W. BRODERICK, who holds equally strongly that a faulty metabolism is an essential factor in the disease, would find not a few to agree with him in a view which, in the present state of our knowledge, is somewhat speculative and lacks the simplicity of the theory of local origin. Yet this simplicity may be only apparent and even misleading. It would be unwise to rest content with such an ætiology without exploring thoroughly the possibility of a constitutional element. Much has been heard lately in America of "traumatic occlusion" as an ætiological factor in pyorrhœa. It is thought by some that when teeth are in faulty occlusion the stress of mastication sets up an irritation of the periodontal membrane which permits subsequent inflammatory changes. A recent announcement in the lay press, couched in glowing terms, stated that Dr. HAROLD BOX, of Toronto, had made a discovery of great importance. It would appear that this observer has investigated the patho-histology of the disease and believes that it may be explained by this conception of traumatic occlusion. The announcement was unauthorised, and criticism must await publication in a professional journal.

The bacteriology of pyorrhœa alveolaris is still obscure. An excellent review of the subject was given last year by Prof. E. GLYNN in a lecture under the auspices of the Dental Board and since published. Although GLYNN considers that streptococci are the chief pathogenic organisms in periodontal infections, he points out that evidence of specificity is lacking. Their invariable presence fulfils one of KOCH'S postulates—they can be cultivated, but these streptococci do not produce the disease experimentally in healthy animals. KRITCHEVSKY and SEGUIN believe on even less conclusive evidence that spirochætes are the causal organisms. BASS and JOHNS'S theory of *Entamœba buccalis* as the cause of pyorrhœa may now be dismissed; there can be no doubt that DOBELL is right in regarding this organism as a harmless commensal of the mouth. With so much unknown about the ætiology and pathology of pyorrhœa, it would be too much to expect unanimity of treatment. Different methods abound and are constantly increasing in number. Each has its enthusiastic adherents and for a time appears to possess magic properties. Each in turn drops out of sight. Clinical experience shows that there is no royal road to the cure of dental sepsis. Neither drugs nor ionic medication nor vaccine-therapy can replace careful instrumentation and mechanical cleansing of the teeth, though they may have ancillary value. Unless the patient is prepared to coöperate loyally in carrying out a definite régime of home treatment, the best efforts of the dentist are of little permanent avail. Much confusion has resulted from the different standards of "cure" adopted by various dentists. The essential lesion in pyorrhœa is a progressive destruction of gum, bone, and periodontal membrane. This leads to the formation of a pocket round the tooth which becomes an ideal receptacle for bacteria and putrefactive debris. A discharge of pus is often present, but is not an invariable feature, as the name of the disease would imply, neither can it be assumed that the presence or absence of pus is a trustworthy index to the gravity of the condition. There is no evidence to show that once the attachment of the periodontal membrane is destroyed it can ever be replaced. Thus conservative treatment may result in arrest of the disease and of its symptoms; there can never be a *restitutio ad integrum*. Conservative treatment, too, has its limitations. A pocket so deep that it cannot be obliterated or kept clean by the combined efforts of dentist and patient is a menace to oral and general health. Extraction then is the safest course. The days when the end and aim of the dentist was to conserve teeth at all costs have happily passed, to be replaced by a standard more consonant with surgical principles.

Vaccine-therapy forms an interesting chapter in the treatment of pyorrhœa. The latest development is to inject the vaccine locally into the gums. This method, introduced by GOLDENBURG, is based on BESREDKA'S assertion that in vaccine-therapy it is necessary for the vaccine to follow the path of the infection for which the treatment is given. FIELDEN BRIGGS, who has recently described[2] the technique, states that two cases under his care were cured. Much depends, however, on the meaning attached to the word "cure." Furthermore, a considerable time must elapse in order to show how far any improvement is maintained. Mr. ARTHUR BULLEID, in a careful paper in the *Dental Surgeon* dealing with the applications of immuno-therapy to dentistry, states emphatically that the vaccines must be autogenous. He divides dental sepsis into two classes: those in which there are no constitutional symptoms, and those in which the dental lesions are definitely associated with such symptoms. He considers that vaccine treatment is specially indicated in the second class, though he holds that in conjunction with local treatment they are often useful in the first group. Time alone must show whether the local injection of vaccines into the diseased tissues offers any advantage over their injection subcutaneously into a neutral area. Indeed, the whole question of vaccine-therapy in pyorrhœa is in a confused state. As BULLEID fairly points out, so long as no causal organism is isolated, vaccine treatment remains empirical, its value being determined by clinical experience. Since it is always associated with local treatment, it is difficult to distinguish the rôle played by the vaccine from that of the local treatment. There is much diversity of opinion among dentists. Some, like BULLEID, consider that vaccine-therapy, used carefully and with regard to bacteriological findings, will do undoubted good in some cases. Others of long experience, after having tested the results of treatment with and without vaccines, have come to the opinion that vaccine treatment is without appreciable influence on the course of the disease. Some who do not agree that the local symptoms are affected by vaccines think they may aid in curing the constitutional symptoms where present. It is evident that our knowledge of pyorrhœa on all points is far from final, for there is a wide divergency of view on the ætiology, pathology, bacteriology, and treatment of the disease. Yet the pessimism which might seem to follow on such a confession is not justified. We agree with Mr. Bayford Underwood, writing in the same issue of the *Dental Surgeon*, that though progress is slow it is definitely advancing. The dentist can even do something to prevent the disease from occurring in many cases by seeing that his intervention, both remedial and prophylactic, is directed to the prevention of food stagnation. The maintenance of nasal respiration is of great importance, for it is an undoubted fact that a healthy mouth cannot exist if mouth-breathing is present. In early cases much can be done by careful treatment, but to be effective the patient must coöperate wholeheartedly with the efforts of the dentist. Provided that intervention comes early before the disease is too far advanced, it is possible to arrest its progress and to ensure a functional mouth. The active and concerted research into dental disease which is now being carried out by the Medical Research Council in coöperation with the Dental Board should hasten the solution of some of these problems.

NEW FACTS IN THE ÆTIOLOGY AND TREATMENT OF MALARIA.

The recent researches of Prof. Warrington Yorke and Dr. J. W. Scott Macfie, reported to the Royal Society of Tropical Medicine and abstracted in The Lancet last week, not only fill in many gaps in our knowledge of malaria, but also furnish first-hand information for the guidance of the alienist inclined to test this remarkable new method in the treatment of general paralysis. Most of the work was performed with the benign tertian parasite (*Plasmodium vivax*), which, undoubtedly, is most suited for injection; the quartan was soon discarded on account of its extraordinarily prolonged incubation period, which may last as long as 54 days, while injection of the subtertian parasite (*P. falciparum*) produced in the solitary case in which it was tried a fulminating and fatal attack.

With regard to the natural history of malaria, so many new facts emerge that it is difficult at the present moment to appraise them all. The unicity theory of the origin of malaria, so tenaciously propounded by Laveran, has received its death-blow. There are three species of malarial parasites which invariably reproduce themselves on inoculation and remain true to type. Then, again, we learn that, contrary to expectation, the repeated subinoculation of malarial blood from man to man through more than 20 passages in no way alters the virulence or virility of the parasites, nor does the diseasse thus produced differ in any remarkable degree from that acquired by the bite of infected anopheline mosquitoes. In the treatment of this therapeutic malaria by quinine there is much cause for reflection, for the authors found, in accordance with previous workers, that inoculated malaria proved to be extraordinarily susceptible to the action of quinine—30 gr. a day for three consecutive days being found sufficient to sterilise the patient of his infection. This rapid action is forcibly contrasted with the experience of Prof. J. W. W. Stephens and his colleagues upon malarial infections contracted during the war. On the other hand, the alleged prophylactic effect of quinine receives a severe blow from which it can hardly recover, for we learn that from abundant experiments the administration of this drug before the bite of an infected mosquito is quite useless, and that its administration must be continued for at least ten days after the infecting feed to prevent the disease from developing. In other words, it is evident that quinine is entirely innocuous to the sporozoites, and the conclusion is reached that the drug exerts its maximum action upon the young trophozoites in the blood-stream, and it is, therefore, most effective in primary infections. The mechanism by which a cure is produced is ascribed to production by the host of immune bodies in response to the antigen formation resulting from the destruction of a considerable number of parasites.

However important the facts related above may be to the tropical worker, possibly of even greater interest to the practitioner in this country is the impartial statement upon the value of the malarial treatment in general paralysis. Of 84 paretics, who have been observed for a sufficient length of time, 27·4 per cent. have been discharged as provisionally cured, while an additional 20·2 per cent. show distinct mental and great physical improvement. The exact mechanism by which this desirable result is obtained by the malarial parasite is not at present by any means clear. If it is effected by a series of regularly repeated protein shocks we are left at a loss to understand how the cerebral sclerosis and the degeneration of the nervous tissue can be permanently affected. All who were privileged to listen to this paper will endorse the congratulation offered by Lieut.-Colonel S. P. James, of the Ministry of Health, upon an important piece of research. The Liverpool School of Tropical Medicine has always maintained a reputation for accurate and conscientious scientific work, and this reputation has been fully maintained, if not augmented, by these remarkable and suggestive investigations, as well as by the lucid manner of their exposition.

◆

HOSPITAL COÖRDINATION IN BIRMINGHAM.

As in other cities, hospital work in Birmingham has somewhat suffered from the multiplicity of institutions. Besides the two large general hospitals, the General and the Queen's with their special departments, there are numerous smaller hospitals serving special interests and making independent appeals for support. The two larger hospitals are connected with the medical school, but the clinical material at the other hospitals with some exceptions is not available for teaching students. For some time there has been a movement towards greater coöperation between the various hospitals. At the recent annual meeting of the Birmingham and Midland Hospital for Diseases of the Nervous System, the most recently founded special hospital, it was reported that a working arrangement had been made with the Queen's Hospital. Each hospital will retain its separate identity and management, but all appointments to the staff of the Nerve Hospital will be made by the Queen's Hospital and the whole of the medical work will be conducted by members of the staff of the Queen's Hospital. This will be a great advantage to both institutions, and the patients at the Nerve Hospital will be available for clinical instruction. An arrangement has also been made between the General and Maternity Hospitals. Heretofore both hospitals have had an external midwifery department, but in future the midwifery department of the General Hospital will be transferred to the Maternity Hospital, the hon. obstetric and hon. assistant obstetric officers at the former becoming members of the staff of the latter hospital. This scheme will prevent much overlapping and will help to reduce the economic burden. Important extensions at several of the hospitals are being discussed, and it is possible that other working arrangements will be entered into in the future. From many points of view it would seem to be an advantage for special hospitals to be closely associated as regards their medical work, but not necessarily as regards their management, with a large general hospital.

Annotations.

"Ne quid nimis."

THE FIRST DENTAL BOARD.

THE Dental Board of the United Kingdom was reminded by its chairman, Mr. Francis Dyke Acland, in his opening address on May 13th, that it was the sixth session and the final sitting of the First Dental Board. He thought that any impartial observer would agree that the past two and a half years of work had been carried through in an earnest and liberal spirit and in friendly coöperation. He could wish that the harmony and coöperation in the profession were as complete as it had always been in the Board. As a commentary on the opinion which he had heard expressed, that practically all persons who previously lived by the practice of dentistry had succeeded in becoming registered, Mr. Acland pointed out that, whereas between 12,000 and 13,000 forms were issued to applicants and nearly 11,000 applications were made, the actual number of dentists 1921 on the Register at the present time was approximately 7736. Probably a few mistakes had been made, but there was no doubt that those who were not justified in obtaining admission to the Register are finding it difficult to maintain their position upon it, and are tending to drop out. He congratulated the Board upon the fact that, although many of the cases submitted had required anxious thought, only two appeals had been entered against their decisions. During the first year of its work the Board had to take proceedings in a large number of cases with regard to "covering"; the fact that no complaints had been received under this heading for some time indicated the practical cessation of this practice.

The year 1923, Mr. Acland went on, was largely occupied in working out schemes for assisting in dental education aand research, although a beginning was made in the previous year, and of giving grants to ex-Service students who were not able to complete their courses by the assistance which they had received from the Government. Courses of lectures were arranged in the spring of 1923, and again this year, dealing with the higher branches of dental science, which had been very generally successful. Loans to students unable to complete their course without financial assistance have been made, and have been undoubtedly useful. The position of dental schools as regards accommodation and facilities for dental training was carefully examined, and, as a result, the sum of £16,000 has been earmarked to assist them. Good relations were established both with the Medical Research Council and the Department of Scientific and Industrial Research, and careful and thorough schemes of research are now proceeding, both on the scientific and on the practical sides of dental work. Towards the end of the year two new educational activities were developed, first by courses of lectures and instruction to new entrants to the Register, which were reported to be well attended and much appreciated; and, secondly, by a scheme of granting bursaries to students of slender means to assist them in taking a full dental course.

As regards prosecutions, proceedings were taken and pressed in 39 cases, convictions secured in every one of them, and fines and costs amounting to £272 and £58 respectively were imposed. The difficult question of arrangements between coöperative societies and dentists was approaching solution, owing to goodwill and common sense on both sides. The Board is now justified, Mr. Acland thinks, in assuming that all practitioners have had a full opportunity of realising the principles to be followed with regard to advertising and canvassing, and in dealing with cases which come before it on this assumption. Steps are being taken for an active campaign through the chief constables to put a stop to unregistered practice. Proceedings have been taken against unregistered persons treating pyorrhœa by prescribing a mouth-wash after examination of patients' mouths. The practice was held to be "giving such advice and treatment as are usually given by dentists," and fines of £100 were imposed.

In conclusion, Mr. Acland gave an estimate of probable future income and expenditure, in order that the Board and Parliament might be in a position to judge whether it would be justifiable to reduce the annual retention fee of £5 which is now charged.

"On the income side," he said, "we may estimate to receive about £45,000 a year, which I do not think will vary very much or very rapidly for some considerable time. I hope that the numbers entering the profession each year may slowly increase, but I think that any increase in this direction may be balanced by the fact that more advanced ages are probably unduly represented on the present Register, and that a good many now on it may find it difficult to maintain their position. Against the £45,000 income, I set first of all the sum of £12,000 to cover our standing charges, such as fees and travelling expenses of members of the Board, printing, salaries and wages, office expenses and legal expenses. The next item is £12,500 for educational and research work other than bursaries, and contingencies in connexion with such work. This is made up as follows:—

Research	£6000
Grants to dental schools	£3000
Propaganda as to the benefits of proper dental treatment	£1000
Post-graduation and Post-registration lectures and classes, and publications on professional dental subjects	£1500
Contingencies to cover inspection of examinations and the holding of prescribed examinations, &c.	£1000

"The two main sums make a total of £24,500, and leave a balance of £20,500 for bursaries. I estimate that a bursar may cost £130 a year, and therefore £20,500 will maintain about 160, or an entry of 40 a year for a four years' course. Before the war, an entry of rather over 250 students maintained a practising list of about 5000. On these figures the present Register of 13,500 will need an annual entry of 700 if it is to be maintained, and a considerably larger number if the practising list is to be raised to 16,000, which is the calculation on the basis of one to every three thousand of the population. The present entry, following upon a very heavy post-war rush, is, as we know, only a small one, but this will no doubt steadily expand. If the figure of only 600 entrants a year be regarded as within practical politics during the period which I am considering, it is clear that if but 40 students a year are helped, the percentage that this bears to the whole number is only between 6 and 7 per cent. I do not think that anyone can suppose that the number of young men and women who would make in every way competent dentists, but who cannot afford without help to enter the profession, will bear this low proportion of the whole number desiring to enter it. I, therefore, cannot regard the sum of, roughly, £20,000 a year for bursaries as being in any way excessive. If the fee were reduced by even £1 a year this amount would be approximately halved, and only 20 students a year could be assisted. Taking these circumstances into account, I am strongly of opinion that there is no sufficient justification for a reduction of the present retention fee. Dentists now on the Register will realise that, although they would have an almost inappreciable annual amount to gain by a reduction of fee, they would have later on very much more to lose if an agitation were to arise, owing to an insufficiency of fully qualified dentists, for the lowering of the standard of the qualification or the setting up of an inferior standard."

The remainder of the session was occupied with the consideration of penal cases.

FORENSIC PROBLEMS OF LETHARGIC ENCEPHALITIS.

THE Danish neurologist, Dr. August Wimmer,[1] has drawn attention to some of the very troublesome medico-legal problems to which lethargic encephalitis has given rise. With increasing knowledge of this disease it is becoming abundantly clear that its acute early stage is but the beginning of much worse things; it is the chronic sequel, the smouldering disease of the central nervous system, which is most to be dreaded. While psychic changes are comparatively rare in adults after an attack of lethargic encephalitis, adolescents and children seem very prone to develop moral and psychic faults which make them a nuisance and even a terror to their surroundings.

---

[1] Hospitalstidende, 1924, lxvii., 177.

In the experience of Dr. K. Winther, as many as 12 out of 25 children suffering from lethargic encephalitis developed more or less gross psychic disturbances. They may, in many cases, be fugitive and difficult to classify, and the boundary-line between the healthy and the morbid mind being often difficult to draw, the physician is hard put to it to know what to do with these patients. They may be too sane for an asylum, but not sane enough to remain at home. In ordinary hospitals they have no place, and considering how numerous these cases are, it may prove necessary to establish special institutions for them. Meanwhile, these patients travel from pillar to post, disturbing the peace, falling foul of the police, and being subjected to psychiatric examination and observation with little result and benefit so long as a more or less permanent resting place is not available for them. Dr. Wimmer illustrates the difficulties associated with such cases by an account of a patient aged 14. In August, 1920, he developed fever, drowsiness, delirium, ptosis, diplopia, and paresis of the right facial nerve. A month later signs of mental deterioration appeared. He was foul-mouthed and quarrelsome, spitting like a lama, and coaxing nurses to him only to strike them in the face or attempt improper approaches. A neurological examination was remarkably negative; his intelligence seemed to be unimpaired, and when he was discharged from hospital at the end of October, 1920, he seemed to have regained his normal mentality. He was readmitted to hospital in April, 1922, because of choreiform disturbances and erotic propensities. Systematic tests of his intelligence showed no gross defects, and he was discharged from hospital. In May, 1923, he again drifted into hospital, this time on the initiative of the civil authorities with whom he had come into conflict on account of assaults on young girls. He admitted that these assaults, or attempted assaults, were the outcome of momentary impulses, but a neurological examination showed nothing definitely abnormal. Cases such as this are so common that the problem of dealing adequately with them is most serious: to deprive such persons completely of their liberty seems hardly justifiable, yet to leave them uncontrolled is to invite tragedies such as that of Vera Hoad. Till we know more of post-encephalitic psychopathy and its prognosis, we run grave risks of being unjust to the patient, the community, or both.

THE SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS.

IN an address, delivered before the Welsh National Memorial Association to which he is consulting surgeon, and published this week in our columns, Mr. H. Morriston Davies outlines the indications for operative treatment in pulmonary tuberculosis. For 10 or 12 years he has himself been performing various thoracoplastic operations, but only recently has he been able to get such work organised on a proper basis. Nevertheless, surgical methods should be available for rich and poor alike, and Mr. Davies contends that if surgical methods were generally adopted in sanatoria it would imply a large increase in staff and equipment. The results in his experience are brilliant. Of cases in which a complete pneumothorax could be induced, over 70 per cent. became fit to return to work and more than 50 per cent. of of his thoracoplastic patients were freed from their symptoms. Apart from other indications the artificial pneumothorax justifies itself by relieving a patient from the fear of a return of serious hæmoptysis. Surgical methods have had more vogue abroad and, thanks to the initiative and skill of Prof. F. Sauerbruch, the University Surgical Hospital of Munich has for many years been the leading centre for plastic operations on the lungs. A monograph[1] recently published by his assistant, Dr. Alfred Brunner, is an instructive summary of the advances made during 1918–22 in this promising branch of surgery. Important information has been gained during these years with regard to the technique of the operation and the avoidance of the many false steps, any one of which may convert success into disaster. As a considerable number of cases have now been operated on at Munich, and these cases have been carefully classified, it is already possible to define clearly the indications and contra-indications for thoracoplasty, and it is probable that many of the patients operated on a few years ago by Prof. Sauerbruch would, in the light of his more recent experience, have been considered unsuitable for this most exacting operation. Dr. Brunner's classification of the 117 cases, operated on in the period under review, brings this point out very clearly. In his first group there were 35 cases in which the disease was almost entirely unilateral, afebrile, and fibrotic; it had lasted for years and had shown a definite tendency to heal by fibrosis and retraction. In this group he had to record only three unsatisfactory results. Of the remaining 32 patients, six were improved, another 12 were rid of their tubercle bacilli, and 14 were cured. It would be no exaggeration to describe these results as brilliant. His second group included 43 cases whose characteristic features were a sub-febrile temperature, suspicious signs of activity in the opposite side, and other phenomena suggesting that there was an exudative element in the disease. In this second group he had to record two early and four late deaths, and five other cases in which the disease became worse or remained stationary. There were 14 cases showing improvement, 12 became sputum-negative, and six could be regarded as cured. It will thus be seen that 32 of the 43 patients benefited from their thoracoplasties. Far worse results were obtained among the 39 patients belonging to the third group, the distinctive features of which were rapid progress of the disease, a high temperature, and, in most cases, great general debility. None of these 39 patients was cured, and only 11 derived any benefit from the operation. This hastened the fatal issue in many cases, 21 of the patients dying within a year of the operation, and 10 of them in immediate connexion with the operation. Another lesson of Dr. Brunner's monograph is that this operation requires great practice and dexterity if it is to achieve the best results it is capable of; the duration of the operation is a most important factor, and the leisurely-fingered surgeon would do well to leave it alone.

HOSPITAL BEDS FOR CHILDREN IN SOUTH LONDON.

CHILDREN'S hospitals play a very important part in the health of the metropolis, yet the accommodation for this section of the community is most meagre. On the south side of the river there is actually only one cot for 12,560 head of the population, as compared with one cot for 3523 per head on the north side; and this difference is steadily increasing owing to migration of the occupants of demolished small tenements. Moreover, the population is poorer on the south side than on the north side. The annual report of the Belgrave Hospital for Children (Clapham-road, S.W.) for the year 1923, which has just been issued, clearly shows that of 1496 patients admitted to the wards during that year, some 600 came from Lambeth, about half that number from Wandsworth and Camberwell respectively, smaller numbers from Southwark, Battersea, and the remaining South London boroughs, while only 16 came from North London and 32 from places beyond. This means that 96 per cent. of the total beds in the hospital served the needs of South London and 86 per cent. the needs of the five boroughs in the centre of which the hospital stands, an indication of local usefulness which is something of a record. The total ordinary income of the hospital for 1923 was £9809 as compared with £8831 in the previous year, and the total ordinary expenditure was £9840 and £10,251 for these two years respectively, showing a drop of £411 for the year with which the report deals. The evidence of careful husbandry is grateful, but it is lamentable that economy should have to be so strictly enjoined. The medical report gives the percentage mortality of the 1496 patients in 1923 as 6·21 per cent., and of the 1152 patients in 1922 as 8·1 per cent. Of six patients operated on for congenital pyloric stenosis all but one recovered. The report should be studied and its lessons taken to heart by all those who control purse-strings on the right bank of the river which industry has rendered so unlovely.

EFFECT OF PATHOLOGICAL SERA ON PLAIN MUSCLE.

It is well known that serum contains a substance which increases the tone and augments the rhythmical movements of surviving plain muscle—e.g., in the arterial and intestinal muscles. In the current number of the *Quarterly Journal of Experimental Physiology* Dr. Lena C. Adam records observations made on intestinal muscle only. The tissue used was a slip of longitudinal muscle from the lowest 2 inches of cat ileum, either fresh or on the second day, after being kept in the ice-chest; the animals were killed by chloroform or coal-gas. It was found that normal human serum contains a substance which causes a constant rise in tone when applied to plain muscle. The augmentor substance occurs in serum, citrated blood, citrated plasma, laked washed red cells, and fresh uncoagulated blood. A similar rise in tone was obtained with serum from cases of diabetes, scarlet fever, diphtheria (convalescent), pernicious anæmia, syphilis, and some cases of nephritis, malignant disease, and afebrile tuberculosis. An increased effect was obtained with serum from exophthalmic goitre, febrile tuberculosis, six out of eight cases of malignant disease, six out of nine cases of nephritis, and one case of influenza. A less marked rise of tone occurred with serum from one case of myxœdema, and was increased up to normal after thyroid feeding. It would be of great interest if, as the outcome of these observations, some factor could be found common to pathological states of which the sera has an effect greater than normal.

THE CASSEL HOSPITAL FOR FUNCTIONAL NERVOUS DISORDERS.

The methods of treatment in use at the Cassel Hospital for Functional Nervous Disorders, Swaylands, Penshurst, are familiar to those acquainted with an excellent manual[1] published by its medical director last year. We know that Dr. T. A. Ross is not committed to any one method or to any one school; that different methods are used for different cases, but that in the great majority of cases psycho-analysis of any kind is avoided. The second annual report, whose issue we recorded last week, affords the first real opportunity of estimating the results obtainable by the "common-sense" means of treatment which he has advocated. They are most encouraging. Among the 113 patients in the largest of the classified groups—the psycho-neurotics—of 97 individuals who have sent replies from 6 to 20 months after their discharge, 75 are better and 29 state that they are absolutely well; 18 report that they are no better, and the remaining four are better but do not attribute their improvement to their treatment at the Cassel Hospital. The criterion of improvement is whether they are "fitter to face the world or not"—surely the most practical touchstone of all. The director in this report has nothing new to say on treatment, but he emphasises the fact that practically all psycho-neurotics are aware in some measure of the experiences in which their disease has had its origin, and adds: "History-taking in minute detail appears . . . to be infinitely more fruitful than the process which is usually called psycho-analysis." It is not denied that free association methods will sometimes discover these lost memories when history-taking has failed; but the year's work has tended to increase Dr. Ross's belief that the vast majority of the complexes so discovered are of no value in treatment. He is convinced further, from observation on several patients, that certain of the stereotyped complexes, such as the Œdipus complex, are not arrived at spontaneously by the patient; and a little care in questioning patients who have been analysed elsewhere has convinced him that many analysts impose Freud's views on their patients, and that there is not a great deal of true analysis being done. Another interesting point in the report is that patients with gross hysterical disability have been treated by "the method of direct persuasion after the history had been taken and the position explained." Dr. Ross deprecates the use of all physical aids, such as electricity. The number of his cases in 1922 was only seven, but six of them were completely cured and none had relapsed. Of the cases of psychosis, only 26 were considered suitable for treatment; 11 improved greatly while in the hospital and in nine the improvement has been maintained; of the two who relapsed one has again recovered and the other is again under treatment. The report states that at least six of these 11 patients would sooner or later have required treatment in a mental hospital if they had not been under treatment at Swaylands. The principle is consistently maintained at this hospital of refusing to express any conclusion as to whether a patient has or has not benefited from his stay there until at least six months after discharge; consequently the report deals with those patients who were treated in the hospital during the year 1922, from whom accounts have been received during 1923—182 individuals in all. There is ample evidence that the hospital is doing good work, and that it is fulfilling the purpose of its founder by aiding a type of patient whom it is almost impossible to improve in a general hospital.

A CANADIAN SYMPOSIUM ON CANCER.

The last issue to reach us of the *Canadian Practitioner* (Vol. XLIX., No. 3) is a special "Cancer Number." There are in all 17 original articles by American, British, Canadian, and French authors, and the subjects range over the whole field of causation, prevention, and treatment of the disease. A general review of these articles is given in an editorial, and we think there will be wide endorsement of the commendation of the article entitled "The Influence of Radiation Therapy on the Study of Cancer," by Prof. James Ewing, of Cornell. This article will be read with pleasure and interest by many others than radiologists, for Prof. Ewing emphasises the fact that the radiation therapy of cancer has elicited many peculiarities in tumours demanding further study from biologists and physiologists. He briefly reviews the reaction phenomena which are a sequel to the irradiation of human tumours, and divides them into various categories. The first are the embryonal tumours which have a high degree of radio-sensibility; in these radiation may cause disappearance of the tumour without appreciable damage to the normal tissues of the host. The second are the cellular carcinomas, derived from adult cells which are not so radiosensitive and, while the primary results of radiotherapy in these cases are often brilliant, few complete cures are obtained. The majority of malignant tumours are, however, not so radiosensitive that the desired result can be brought about without some damage to the normal structures; in these a definite caustic action cannot be avoided. Occasionally the radiologist has to be content with slowing up or holding in check the malignant growth; Prof. Ewing is careful to point out, however, that this is, in many cases, a by no means negligible thing, for such treatment may in time transform a malignant tumour into a quiescent and comparatively innocuous process. The whole number is deserving of study, and if we cannot completely subscribe to the view expressed by the editor that "the causes of cancer are to a large extent known," and still less to the view that "cancer can be prevented in a large proportion of cases, including cancer of the stomach"—we can well believe that time will achieve this unity of opinion.

CRIMINAL RESPONSIBILITY OF THE INSANE.

Mr. Donald Carswell's summary of proposed changes in the law of criminal responsibility of the insane, delivered and discussed at a meeting of the Section of Psychiatry of the Royal Society of Medicine, is given in another column. It forms a valuable commentary on Lord Darling's unsuccessful attempt (outlined under Parliamentary Intelligence, see p. 1084) to obtain legislative recognition for the defence of uncontrollable impulse. In asking the House of Lords to give a second reading to his Criminal Responsibility (Trials) Bill, Lord Darling modestly spoke of himself as the franc-tireur whose sniping brings on a pitched battle. Certainly the heavy artillery was brought to bear on the sniper. The weight of high judicial opinion proved hostile. Lords Sumner, Cave, Haldane, and Dunedin spoke against the proposal. The Lord Chief Justice stated that, out of 12 King's Bench judges whom he had consulted, 10 were opposed to it, one was in favour of it, and one was doubtful. In the circumstances Lord Darling could do nothing but withdraw his Bill. The main line of attack was the danger of the defence of uncontrollable impulse being set up in many serious charges, especially in crimes due to anger, vengeance, or sexual passion. There is evidently a judicial fear that the conduct of trials will be handed over to the medical profession, who will argue insanity from the nature of the offence. There is also a fear of weakening the citizen's power of resisting temptation. "Who is to decide," asked Mr. Justice Avory in charging the Leeds Grand Jury the other day, "whether an impulse was uncontrollable or merely not controlled? The law is there to teach people to control these impulses." Lord Darling's Bill was, in part, merely declaratory. He had some ground for contending that the defence of uncontrollable impulse is already recognised in English law. Sir James Stephen thought and taught so; Lord Denman said so in Oxford's case as long ago as 1840; the late Mr. Justice Bray declared so in Fryer's case in 1915; and Mr. Justice McCardie advised the jury so in the case of Ronald True. There are doubtless plenty of judicial decisions and opinions to the contrary, but it is a pity that the law does not make up its mind one way or the other. In favour of Lord Darling's statement of the principle one might further cite the established practice of the courts of Italy and of Germany and of South Africa and Queensland. Finally, there is the strong opinion of Lord Justice Atkin's committee of last year. That committee recommended that it should be recognised that an accused person "is irresponsible for his act when the act is committed under an impulse which the prisoner was by mental disease in substance deprived of any power to resist." Who were the rash and thoughtless committeemen who recommended what the recent speakers in the House of Lords denounced as such a difficult and dangerous doctrine? Two of them, Sir Edward Troup and Sir Ernley Blackwell, were the highest possible authorities on the administration of the criminal law as seen from the Home Office side. Four of them, Sir Edward Marshall-Hall, Sir Herbert Stephen, Sir Richard Muir, and Sir Archibald Bodkin, were men whose names guarantee that all possible points of view, whether of prosecution or defence, were well known and fully considered. Apart from the learned chairman, the three remaining members were all ex-law officers of the Crown, Sir Ernest Pollock (now Master of the Rolls), Sir Leslie Scott, and Sir Thomas Inskip, all experienced in conducting and advising upon important criminal trials. The committee was of exceptional legal and administrative strength. Is it likely that their recommendations would be too difficult to work or too dangerous to execute? Neither the report of Lord Atkin's committee nor the proposals in Lord Darling's Bill could be described as entirely satisfactory to the medical profession, but they were a step in the right direction.

Lawyers and judges would probably admit that their views are not scientific. Their attitude is one of confidence in administration and distrust of fine shades or progressive principles. "How," they ask, "are we to define insanity? Trust the wisdom of our judges, trust the common sense of our juries, trust our expert administrators at the Home Office, and all will be well." The anomalies of the law were well illustrated by the second clause of Lord Darling's Bill. As has been pointed out in these columns before,[1] the Trial of Lunatics Act of 1883 encourages a verdict of "Guilty but insane." Now to be guilty involves crime, and to commit a crime involves having what the law calls a *mens rea*, whereas to be insane involves the absence of a sense of right and wrong. The absurd verdict of "Guilty but insane" means little more than "Guilty but innocent." Lord Darling proposed to substitute "Not guilty because insane," but this proposal has fallen with the rest of the Bill.

ISOLATION OF LEPERS.

The campaign recently initiated at the Mansion House for the care and treatment of leprosy throughout the British Commonwealth has naturally led to an increased interest in the existence of cases of leprosy at home. Emphasis has been laid on the method of segregation to limit the opportunities of infection, and so to combat the further spread of leprosy, and the question has very naturally been asked as to whether the lepers resident in this country should not again be segregated, as they were when the first leper-house was established at Nottingham in the year 625 A.D. Paris has recently woken to the possible danger of the spread of the disease in that city, to which at least 200 lepers have drifted from foreign countries, and Prof. Jeanselme has asked the Permanent Leprosy Commission to study anew the prophylactic measures desirable to prevent the spread of the disease in France. It is admitted that the method of infection in leprosy is practically unknown—hitherto it has proved impossible to infect animals—while the classical example of Father Damien, who wilfully and wittingly succumbed to the disease after 16 years' sojourn with lepers on one of the smaller Sandwich Islands, is still fresh in the popular imagination. In the United States of America a Bill was presented to Congress in 1905 with the aim of setting up a national leprosarium, although nothing came of it at the time. One of the Eastern States has its leper asylum in Boston Harbour. We think that anxiety in this country would be at once allayed by a cold study of fact. Although leprosy is not here a notifiable disease, yet successive Ministers of Health have given assurance in the House of Commons that the approximate number of cases of leprosy in this country is known, the total not reaching three figures. Since 1914 a number of cases have been isolated at St. Giles's Homes in Essex, which can accommodate six patients at a time; here local anxiety is giving place to a feeling of pride in possessing a benevolent instrument. In all these cases, wherever opportunity has offered of complete investigation, the source of infection could be definitely traced to previous sojourn outside the country. There is scarcely any evidence of leprosy having been acquired in Great Britain during a century or more; the last authentic case of endemic leprosy died in the Shetland Islands in 1798. The two or three cases in which home infection was presumed 40 or 50 years ago were instances of prolonged and intimate contact which is quite excluded by present-day conditions. Hence, from the public health point of view, there would be no justification in segregating such cases as we have amongst us. The disease itself is sufficiently distressing without adding thereto the ferocious measures of the Middle Ages, when segregation led to a morbid fear of chance contacts. The Ministry of Health has recently had occasion to investigate an instance in which one of the nurses trained at St. Giles's Homes has undertaken, on her own initiative and expense, to furnish an asylum for some of these unfortunate persons, and to provide them with access to the most modern medical treatment. It is, we admit, uncongenial to many people to live within sight of their less fortunate comrades, whether they be morally, mentally, or physically afflicted. We can with good conscience assure them that there is no hygienic or public ground for anxiety or interference, though it would hardly be denied that at some places—for example, health resorts—the presence of a home for lepers might damage local interests. Where this is not so interference with a deed of mercy would be deplorable. It is only the very rich or the very heartless who can elude the reminder of such inequalities in our present social life.

NEW METHODS AT BUXTON.

The formal reopening by the President of the Royal College of Physicians of London of a remodelled installation of hot baths at Buxton is an event of no little importance in British hydrology. It cannot be denied that, under new methods of investigation, the spas of all countries are being classified afresh, and true progress consists in the well-considered development of the special indications for each water. It is not always easy to define these *differentiæ*. Recent researches carried out by spa practitioners in the mineral waters hospitals, in which we are glad to see that Buxton is bearing an honourable part, have been recorded in the *Archives of Medical Hydrology*. They reveal unexpected actions and differences between springs. The Committee for the Study of Medical Hydrology in Great Britain has, during the past year, arranged lectures at the University of London and at various medical schools. These have been set up in the hope of familiarising medical men with the practice of hydrology in Britain and other countries, and also of instructing senior students in the principles upon which this practice is founded. It can hardly be doubted that even a few men, qualified by serious study, could do much to advance both the science and practice of hydrology in any country. Such opportunities for special training seem especially desirable, and even necessary, in England, if the British spas and the modes of treatment which they offer are to be looked upon, in Sir Humphry Rolleston's words, as a national asset. To utilise such resources in the proper manner is, we think, both a medical and public question, and ought no longer to be left to unassisted efforts of individuals, or even of enlightened public authorities.

THE COMING VOLUNTARY HOSPITALS CONFERENCE.

The best method of completing the investigation into hospital accommodation will be the principal subject of discussion at the Conference of Local Voluntary Hospital Committees, which is to be held on June 18th. In order to focus the points for discussion at this Conference, the Voluntary Hospitals Commission has asked the local committees to obtain from each hospital in their area particulars of beds, length of stay, and waiting lists. The local committees are also asked to furnish reports on the following points:—

1. It is not an uncommon practice for patients awaiting hospital treatment to put down their names on the waiting lists of two or more hospitals. The difficulty, therefore, in computing the number of persons awaiting hospital treatment is the elimination of duplicate entries. The local committees should indicate whether there is any reason to suppose that such duplication exists, and if they are able to obtain exact figures after eliminating duplicate entries, these should be included in their reports.

2. The views of the committees on the extent of the need of further beds in terms of the several classes of beds specified in the questionnaire. (The Commission would particularly wish to know the views of the committees on the question of how far the need in their areas should be met by the provision of hospital beds or alternatively by the provision of more recovery or convalescent beds.)

3. The observations of the committees on the prospects of the hospitals succeeding in carrying out any scheme they may have in view for providing further beds and for maintaining them. In this connexion the Commission would be glad to know whether the committees have formed any opinion as to any alternative method of providing additional beds in their area.

4. What convalescent accommodation there is available for the inhabitants of the area, apart from beds controlled by the hospitals.

5. Whether there is any arrangement for utilising vacant Poor-law infirmary accommodation to supplement the voluntary hospital accommodation in their area.

6. The observations of the committee regarding any vacant beds there may be in the hospitals in their area, particularly as to how far vacant beds could be utilised —e.g., by a system of transfer of patients.

7. Whether the committees have conferred with the medical officers of health in their area, and what views the latter may have expressed on the question of hospital accommodation.

Local committees are also asked to make any suggestions as to how far the difficulties created by shortage of accommodation could be met by means of coöperation with areas adjoining their own.

RADIOGRAPHY OF THE PYLORUS.

The interpretation of pyloric radiography tends to become more precise. Herrnheiser[1] in discussing X ray appearances of the pylorus and the pyloric antrum in the diagnosis of ulcers in these situations, draws attention to four morphological changes that occur in these conditions before any actual stenosis becomes manifest—viz., the pyloric or pre-pyloric niche, the contraction and reaction of the pyloric canal, and the formation of diverticula. The pyloric or prepyloric niche is situated usually on the lesser curvature, and varies in size up to about ½ cm. It is a sign of a simple ulcer, though malignancy cannot be absolutely excluded. If present, it is very strong evidence of an ulcer in the pyloric region. Contraction as opposed to actual defect, and analogous to hour-glass contraction of the body of the stomach, is of more frequent occurrence than the already mentioned sign, and is usually found along the greater curvature about ½–2 cm. from the pylorus. It remains unaltered in size, has clear-cut edges, and its depth may reach 1 cm. or more. In a new growth a somewhat similar appearance occurs, but the edges are diffuse and irregular. Retraction includes a flattening or elongation of the pyloric antrum or canal, and occurs practically always on the lesser curvature; whilst the greater curvature is full and rounded, the canal itself may be excentric or, if the flattening occurs all round, assumes a conical shape and is frequently twice its normal length. The condition may be associated with simple ulceration of the duodenum with or without pyloric adhesions, less frequently with new growth, rarely with a chronic appendicitis. Formation of diverticula occur typically on the greater curvature between the pyloric canal and a contraction area from simple ulceration, and is frequently present in the pre-stenotic stage of the pylorus. Actual pouching from ulceration rarely occurs in the pyloric canal, and is differentiated from a niche by its being along the anterior aspect of the organ. In a malignant ulcer the outline is irregular and indistinct, and there are other obvious changes in the contour of the viscus. The article gives an indication of the direction taken by clinical teaching of German radiologists.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LXXII.

THE TREATMENT OF BILHARZIA DISEASE.

THIS article deals with the cure of the individual affected by bilharzia disease. It is not possible to deal here with measures advocated for the eradication of the disease. However, the cure of a parasitic disease—if a genuine cure there be—is vastly the greatest part of "prevention," particularly in this case, for antimony not only kills the parasite but sterilises the seeds (ova) which spread the disease. According to the latest Egyptian Government (1923) statistics, it is estimated that of the 6,000,000 people who are infected with bilharzia in that country *over* 5,000,000 can be cured by antimony injections alone.

Bilharzia disease (schistosomiasis) is prevalent throughout Africa, some localities of China are heavily infected (Asiatic species), also one island of Japan, the Philippines, and Formosa; it is endemic in the West Indies and some parts of South America. The disease consists in the invasion of the liver by a fluke whose habitat is the portal vein. The parasites descend to the bladder and rectum by the portal tributaries to deposit ova, which thereby reach the exterior world. Intravenous injection is therefore the rational method of directly attacking the worm. Antimony tartrate is an effective cure [1] for all forms of human schistosomiasis (bilharzia). Both potass. ant. tartrate and sod. ant. tartrate are employed, soluble colourless salts, readily sterilised by boiling; they keep well in the tropics. Neither is too "toxic" for intravenous injection. Readily procurable, stable, and inexpensive, they are suitable for the mass treatment of a widespread disease. The sodium salt is less toxic, more soluble, and quite as efficient as the potassium salt.

Antimony tartrate has two distinct actions in schistosomiasis. It kills the ova deposited in the tissues by the worm and afterwards it kills the parasite. The former is the more important action, for the ova spread the disease. It is necessary to investigate the physical condition of the patient before commencing the injections. Bilharzia disease too far advanced, a feeble constitution from whatever cause, and serious cardiac and renal disease contra-indicate this treatment. A few individuals cannot tolerate antimony. These are only discovered by trial. In children and stout people veins are not easily accessible and some skill is needed to inject such cases. Children may be given antimony tartrate per rectum, but this method is of doubtful value; the large single doses which are given (gr. xv.–gr. xx.) make one suspect that little is absorbed. Emetine may be regarded as an alternative to antimony tartrate when the latter cannot be given. It is given by intravenous injections, 1½ gr. repeated 15 or 20 times in a month and a half or two months. It is inferior in efficiency to antimony tartrate and its use, in the necessary large doses, is liable to be followed by cardiac weakness and peripheral neuritis. In the tropics the fæces should be examined for the presence of other helminths previous to commencing injections. If found these should be dealt with first.

The Technique Used.

Two and a half hours after a light meal and two hours before the next, when the stomach is neither distended with food nor exhausted by hunger, is the best time for the injections, which are given on alternate days or three times a week. The commencing dose for an adult is ½ gr. (for children under 10 ¼ gr.). The dose is increased by ½ gr. at each injection till 2 gr. (or 2½ g.) has been reached. The full dose is given, unless contra-indicated, at each succeeding injection. Ampoules containing the various single doses used are made. They are comparatively expensive and are only suitable for private practice. In other cases dispensing errors are avoided by using tablets containing respectively 1 gr. and 10 gr. of antimony tartrate with the appropriate sodium chloride to make a physiological solution. They are made up conveniently and inexpensively by well-known chemists. These can be readily dissolved and boiled in a test-tube in water before the injection. Antimony tartrate can be boiled over and over again provided the water lost in boiling is replaced. The 10 gr. tablets dissolved in 40 c.cm. of distilled water (when procurable) make the solution: 2 c.cm. contain ½ gr., 10 c.cm. contain 2½ gr., and intermediate quantities in proportion. This standardisation is convenient; it is not too concentrated for the veins, and 10 c.cm. contain the maximum single dose. The 10 c.cm. record syringe is generally used.

Needles.—The needle is an important item, iridium platinum (23 mm. by 6 mm.) with short point are the best. For the negro skin, which necessitates a strong needle, stainless steel (24 mm. by 6 mm.) are used by the missionary doctors in Central Africa. Whatever the make, the needle should be moderately fine, sharp, and free from rust, and not more than 1 in. in length. All the apparatus used should be sterilised, the room suitable for an aseptic operation, the light good, and the patient lying down. In certain Egyptian hospitals the injections are made with the patient sitting, 300–400 injections being given in a morning; this fact indicates the infrequency of untoward incidents attending injections in Egypt. Acetone, ether, or alcohol is used to sterilise the skin. Iodine obscures the vein and is apt to make the site unfitted for subsequent injections. The veins at the bend of the elbow are the most convenient, but any prominent vein in the extremities, the external jugular in children, may be used. A tourniquet is not necessary with a clever assistant to compress the vein; team-work is the key to successful intravenous injections.

The needle *must* be introduced into the lumen of the vein. Cellulitis invariably follows if the solution is injected around the vein. A week or a fortnight in bed and much pain is the result; large fomentations are necessary and not too early incision. A regurgitation of blood into the syringe on withdrawal of the piston is the infallible signal. It is equally important that the needle shall not slip out of the vein during the operation. Beyond the pain experienced by the puncture intravenous injection is a painless operation. If pain is experienced it is wise to assume that the needle-point is not in the vein, but pain *may* be due to too rapid injection or to the solution being too concentrated; slower injection is then the remedy. The careful injector does no material damage to the vein wall provided he uses a sharp clean needle. The same vein may be used at the same spot for the 10 or 12 injections necessary for the course. After the operation the patient should remain lying down for half an hour, when, if he feels all right and his pulse is normal, he may walk home quietly, have a cup of tea, and rest for the remainder of the day; light food may be taken in two hours' time. A local blush is often seen during the injection, and the face and neck may become temporarily flushed. Before the injection is completed a painful, dry cough usually occurs, indicating that the antimony has reached the pulmonary circulation. A metallic taste, a dryness of the mouth, a feeling of constriction in the throat, a tightness of the chest, and later colicky pain in the abdomen are variable incidental phenomena which do not always occur. They are useful signals. If they are severe the dose should not be increased at the next injection; it may be advisable to reduce it. The occurrence of giddiness, headache, sickness, and diarrhœa, call for judgment in graduating the next dose.

---

[1] Prior to 1918 there was no known specific cure for bilharzia, though it is true that in 1916 emetine was being used by Greek doctors in Cairo. Urotropin, ext. of filix mas, boric acid, salol, hyoscyamus, and buchu were the drugs recommended; treatment was palliative and symptomatic, and bed and surgery gave the best results. Surgical complications, tumours and ulcers caused by the deposition of ova, sepsis, calculus, and new growth are still dealt with by appropriate surgery, but it is the practice now to eradicate the active bilharzia infection (parasite and ova) by a course of antimony injections before adopting surgical measures.

Rheumatic Pains.—A very constant symptom occurring during the night following the fourth or fifth injection is "rheumatic" pains in the joints or muscles, commonly the shoulders, caused by the antimony interfering with the metabolism of the liver and thereby allowing into the blood toxic bodies produced by imperfect physiological elaboration. The constant presence in the urine of oxalic acid crystals in excess is noteworthy in this connexion. These pains may be distressing though temporary, and if severe may require a reduction in the succeeding dose.

The first visible effect of the injections on the urine is an increased hæmaturia; later in uncomplicated cases the blood vanishes, the urine becomes normal in appearance, and the native patient, thinking himself cured, is apt not to return for completion of treatment. Punctually on the ninth day the ova in the urine, very much reduced in quantity, become granular. Gradually the live ova (those with outlines of embryonic structures) disappear. After 20 gr. have been given the urine is practically normal. The ova, appearing only at intervals, are granular and dead. Generally speaking, the necessary dose to ensure that both worms and ova are killed is 25–30 gr. for the *adult*.

Four methods for ascertaining whether sufficient antimony has been given have been recommended. None is of precise value: (1) Fairley's complement-fixation test; (2) the eosinophilia differential count; (3) Carlos Franças ovimetric method; (4) the microscopic appearance of ova in the urine. With regard to (1), it is not often possible to procure the necessary antigen, and the "reaction" is positive for some time after the cure. (2) is valueless because eosinophilia is not pathognomonic of bilharzia. (3) is based on the assumption that the female worm responds to the antimony by laying gradually smaller ova, and by measuring the ova the effect of the antimony on the worms can be determined. It also postulates that the antimony-sick-worm lays granular eggs. (4) is satisfactory within limits. The microscope, however, does not disclose the condition of the parent worm. Experience is thus at present the only sure guide in determining the necessary total dosage. Occasionally worms appear to resist even 30 gr. In such cases, suspend injections at 30 gr. and give a second course after an interval. In complicated cases the course of antimony should be given and the complications dealt with afterwards by appropriate medical and surgical measures.

Physiological Action and Tolerance. Idiosyncrasy.

Individuals vary greatly in toleration of antimony. "Coloured races" tolerate it well. Serious intolerance is not common in England, but it occurs more frequently than in Egypt or the Sudan. The initial cough, tightness of the chest, metallic taste in mouth, nausea, sickness, diarrhœa indicate care in graduating the dosage. Moderate intolerance may be overcome by careful slow gradation of dosage, but a patient who has shown marked symptoms of intolerance becomes intolerant to smaller doses. A serious form of "intolerance" appears as "shock," which may occur only after a few doses have been given. Hot-water bottles, blankets, rubbing the extremities are indicated, a diffusible stimulant—two teaspoonfuls of brandy in hot water should be given by the mouth, $\frac{1}{2}$ c.cm. of a 1/1000 adrenalin solution diluted, $\frac{1}{2}$ c.cm. of a 20 per cent. extract of post-pituitary gland solution may be given intramuscularly. Digitalin, 1/50 gr., is useful to stimulate the heart's action. It is wise to be alert but not over-anxious on such occasions. When the condition of the patient has improved, a small cup of strong coffee, after being put to bed, is useful. Antimony tartrate used with caution and circumspection may then safely be employed for the eradication of bilharzia. But if this useful drug is employed empirically or in a commercial spirit it is bound to fall again into disrepute.

Medicine and the Law.

HARNETT *v.* BOND AND ADAM: JUDGMENT OF THE COURT OF APPEAL.

CONSIDERED judgments in this case were delivered by Lords Justices Bankes, Warrington, and Scrutton on May 16th. A summary of the arguments submitted to their lordships will be found in THE LANCET of April 26th, pp. 870–872. The results of the judgments now delivered are that in the case of Dr. Bond the judgment of Mr. Justice Lush for £20,000 against him and Dr. Adam jointly, is set aside, but so far as it related to Dr. Bond, a new trial is ordered to be confined to the liability of Dr. Bond in respect of the alleged detention of the plaintiff at the offices of the Commissioners in Lunacy and of the period which ended when Dr. Adam had decided after the plaintiff's return to Malling Place that he should be detained there under the original reception order. As to this, Lord Justice Warrington said that there was no evidence on which the jury could arrive at the conclusion that Dr. Bond acted otherwise than in the belief that he was acting in Mr. Harnett's interest. This presumably is intended as an intimation that, according to his lordship's view of the evidence, the action of Dr. Bond was not more than technically an infringement of the plaintiff's liberty. In the case of Dr. Adam, verdict and the judgment of Mr. Justice Lush are set aside and judgment entered for this defendant with costs of the trial and of the appeal. Dr. Bond is to have the costs of his appeal, and with regard to costs to be granted at the new trial ordered a special order was made by the Court of Appeal as to the costs of the first trial, limiting the costs to be recovered under this heading by the plaintiff (if the plaintiff should succeed in the second trial) to such as would have been incurred if the claim in the first trial had been against Dr. Bond alone and in respect of the period above indicated for which alone Dr. Bond is to be deemed liable. This limitation of the costs of the first trial to be granted in the event of the result of the second trial being adverse to Dr. Bond was imposed by the Court of Appeal because, as stated by Lord Justice Bankes, the costs of the first trial had been "greatly increased by the form and extent of the plaintiff's claim against Dr. Bond."

Lord Justice Bankes, before summarising the facts of the case and in commenting upon its importance to the medical profession and to the public, pointed out that Mr. Justice Lush had decided that a person who in the view of a jury had acted without sufficient care, with the result that another person was detained under the Lunacy Laws as being of unsound mind, could be held liable and mulcted in damages, because a third person, whose duty it was to have the patient discharged if sane, did not do so, and this although the person, who continued to detain the patient, acted in good faith and in the honest discharge of what he conceived to be his duty. With regard to the detention by Dr. Bond, his lordship referred to that defendant and his secretary as agreed that when Mr. Harnett called at the offices of the Commissioners he was manifestly unfit to take care of himself or to be allowed out any longer on probation. After describing the manner in which evidence covering the whole of the subsequent period of detention had been introduced at the trial, Lord Justice Bankes said that the long-drawn-out story of the plaintiff's detention had enabled counsel to appeal to the sympathies of the jury, and to produce an atmosphere in which the sufferings of the plaintiff monopolised attention.

As to the condition of the plaintiff's mind on Dec. 14th, 1912, the jury had found him to have been sane, but no question had been put to them as to his sanity with regard to the subsequent period from December, 1912, to October, 1921, and it was difficult to see how, without any finding in the plaintiff's favour as to that period, damages could have been awarded him in respect of it. However, the jury must have considered him sane during that period. There had been no argument on behalf of the defendants before the Court of Appeal to the effect that the verdict as to the plaintiff's sanity on Dec. 14th, 1912, was against the weight of evidence, so no opinion would be expressed as to that.

Turning to the main question affecting Dr. Bond, whether his liability, if any, for the plaintiff's detention extended to the whole period from the time when the plaintiff was taken back to Malling Place up to his escape from a different institution in 1921, his lordship pointed out that this was a vital point. He read extracts from the summing up and judgment of Mr. Justice Lush, who had refused to accept the argument that any subsequent proceeding in connexion with Mr. Harnett's detention had constituted a *novus actus interveniens* breaking the chain of causation. Mr. Justice Lush had referred to the certification of Mr. Harnett in November, 1913, as "mere machinery" for avoiding the necessity of a new reception order; and had drawn a distinction between an act of omission (omitting to recognise the plaintiff's sanity) and an act of commission, the latter alone being capable of being interpreted as *novus actus interveniens*. Lord Justice Bankes declined to draw any such distinction in the plaintiff's case, or to find that the proceedings necessitated by the Lunacy Acts were not acts of commission. He could not look on the serious act of certification as mere machinery and found the chain of causation broken in many places. He could not hold that the jury could take into consideration the whole period of the plaintiff's detention in assessing damages. If his lordship's view as to this was right the verdict and judgment against the two defendants as joint tortfeasors must be set aside.

Proceeding further to discuss the question of the damages awarded, Lord Justice Bankes was of opinion that they were based upon misapprehension of the defendants' liability and that the attempt made at the trial to apportion them must consequently fail. He proceeded to refer to the Lunacy Acts of 1890 and 1891 and to the scheme of legislation embodied in them. Lord Lindley in Regina *v.* Whitfeld (15 Q.B.D., 122, at p. 150) had described the powers granted by the Lunatic Asylum Acts of 1853 to justices of the peace and medical men as due to the theory that they could be trusted; this was equally true of the later Acts. The reception order justified Dr. Adam in receiving and detaining the plaintiff whom he might have recaptured under it if he had escaped. His lordship described the processes by which a reception order is continued in force under Section 7 of the Act of 1891 by successive special medical reports to be made by the medical officer of the institution in which the patient is detained. He quoted Lord Denman (In re Shuttleworth, 9 Q.B., 657, p. 658) as saying that double protection had to be afforded against improper confinement on the one hand, and on the other against danger from a lunatic being unrestrained.

With regard to the question whether the liability of Dr. Bond should extend beyond the sending for the patient at his request by Dr. Adam, his lordship looked upon the Lunacy Acts as conferring on the medical man in charge of a patient a daily and hourly duty of satisfying himself of the patient's need to be confined; and in his opinion every decision come to by a medical man, by a Commissioner, by a visitor, or a member of a visiting committee of itself amounted to a *novus actus interveniens*. With regard to the view that these decisions in Mr. Harnett's case had merely been the omission to detect his sanity, his lordship suggested the comparison of a wrong diagnosis of a case of scarlet fever as measles. That would be to make a wrong diagnosis, and would rightly be so described, but according to the point of view adopted it might equally be said to be the omission to make a right diagnosis. In any case the defendant, Dr. Bond, could not be held responsible for the opinions formed by Dr. Adam after the plaintiff had passed back into his hands.

With regard to Dr. Adam, his lordship carefully examined the effect of the reception order and of the probation order granting leave of absence, and declined to treat the latter as giving complete liberty for a full period of 28 days. It was an intimation by the medical officer, sanctioned by two visitors and consented to by the person who applied for the reception order, that the powers under the order would cease to be exercised by the medical officer unless it became necessary that they should be. He could not interpret the words "take back" in the probation order as merely equal to "receive back." He was further of opinion that Dr. Adam was protected by Section 330 of the Act of 1890 if he had acted with reasonable care. He could see no evidence of want of care on the part of Dr. Adam, and the fact that he had not personally gone to fetch the plaintiff back was an example of a comparatively unimportant point to which undue weight had been assigned at the trial. The judgment against Dr. Adam must be set aside and judgment entered for him with costs.

The case of Dr. Bond was on a different footing. Liability on his part had been admitted, but the damages had been wrongly assessed. Judgment was therefore given for a new trial in the case of Dr. Bond, the judgment given by Mr. Justice Lush being set aside, and the scope of the new trial granted being laid down as stated above.

Lord Justice Warrington, in giving judgment to the same effect, said that as liability for the plaintiff's detention had been admitted on behalf of Dr. Bond, so far as he was concerned the question was whether the damages were excessive. Dr. Adam in taking the plaintiff back had acted on the authority of the statute, the reception order, and the probation order, and was not liable to proceedings if he had acted in good faith. The assessment of the damages was wrong. The detention of the plaintiff after he left Malling Place was directly caused by the action of the various medical officers, Commissioners, and visitors who had the necessary power to release or to detain him according to his mental condition. Dr. Bond neither controlled these persons nor Dr. Adam, all of whom could have released the plaintiff. As to the £5000 damages allocated in respect of the detention at the Commissioners' offices, the sum, in his opinion, was excessive. Some of the jury's answers amounted to a serious imputation on Dr. Bond, and there was no evidence to justify them.

Lord Justice Scrutton spoke of the danger of confusing the issues raised at the trial which was not a Royal Commission to inquire into the working of the Lunacy Laws as applied to Mr. Harnett's case. If it had been so it might be suggested that the judicial inquiry preceding the reception order might be more precise in its procedure if the alleged insane person were informed of the charges against him and given the opportunity to answer them. His lordship referred in detail to some of the acts alleged against Mr. Harnett, and pointed out that for eight or nine years visitors and medical men independent of Dr. Bond had examined him. The liability of each defendant ceased when the detention was continued by the legal act of a person appointed to continue or, if he thought proper, to stop it. Dr. Bond had no power to detain the plaintiff and acted illegally in doing so, but his responsibility ended when that of Dr. Adam began, and as to Dr. Adam there was no evidence that he had not acted with reasonable care. In the case of Mr. Harnett the judge and jury no doubt desired to compensate him for wrongs they believed him to have suffered, but a careful examination of the legal position was called for, and the Court must not be turned aside by appeals suggesting that the Lunacy Acts might in a particular case bear hardly upon an individual or upon the community.

The order made by the Court of Appeal as to costs is referred to above. It was further ordered that the sum of £5000, ordered by Mr. Justice Lush to be paid to Mr. Harnett, must be repaid, as a condition of the order for a new trial. An application for costs from Dr. Adam on the higher scale was not acceded to. An intimation was given that the question of an appeal on behalf of Mr. Harnett to the House of Lords would have to be considered by his advisers.

THE SURGICAL TREATMENT OF CANCER OF THE BREAST.

THIRD MEMORANDUM OF DEPARTMENTAL COMMITTEE OF MINISTRY OF HEALTH.

THE third[1] of the series of reviews summarising the position of modern knowledge and practice in regard to different aspects of cancer, now being issued by the Departmental Committee on Cancer of the Ministry of Health, relates to cancer of the breast and the results of surgical operation in connexion with this condition. One of the first undertakings of the Committee was to arrange an exhaustive study of existing surgical literature, home and foreign, which bears on this subject. This considerable task, which has involved the analysis of records of upwards of 20,000 cases, has been undertaken for the Committee by Dr. Janet Lane-Claypon. The presentment of this analysis requires some little time, but meanwhile some important conclusions to be deduced from it already stand out clearly, and have confirmed the Committee in their belief that public advantage will be gained by the issue of the present memorandum.

Facts which should be Recognised.

The memorandum reviews the general position at which surgery has arrived in the case of this form of cancer, and states certain facts which the public should recognise if operative treatment is to yield the success which in favourable circumstances and under modern conditions it is capable of yielding.

The first section deals with immediate operation mortality past and present, and with the duration of convalescence. It is stated that deaths directly attributable to the operation, if performed by skilful surgeons and in well-equipped institutions, have been reduced in breast operations to a fraction of 1 per cent. At the present time even more extensive operations heal, as a rule, without any suppuration and the patient is out of bed in about a fortnight.

In the second section on the natural course of cancer of the breast, the well-known symptoms—age incidence and course of the disease—are set out. There is reason to believe that the upper and outer quarter is the commonest situation in which cancer appears, while the nipple is the rarest, the other portions occupying intermediate positions in this respect. The matter is important because the severity of the disease bears a relation to the portion of the breast affected. The fact that in its early stages cancer is usually unattended by pain is again emphasised.

For many reasons the natural duration of cancer of the breast is difficult to state with precision. Thus (1) the onset frequently cannot be fixed with any degree of accuracy; (2) amongst cases of cancer, even in women of the same age and of the same habit of body, some run an acute, others a chronic, course; and (3) the age at which the patient becomes affected appears to exert an important influence upon the natural course of the disease: cancer takes, on the whole, a more rapid course in the young person than in the old. If cancer of the breast supervenes during pregnancy or lactation the course of the disease may be abnormally rapid. While subject to these variations, the average natural duration of a case of cancer of the breast appears to be a little over three years.

The close relation between cancer and antecedent chronic inflammatory disease of the breast is discussed in the third section; this relation, coupled with the fact that a non-malignant tumour of the breast may remain so for a long period of years and ultimately pass into undoubted cancer, must have a bearing on the advisability or otherwise of operation in diseased conditions of the breast other than cancer.

On treatment of cancer of the breast, which is the subject next dealt with, it is stated as being beyond question that, at the present time, early surgical operation affords the one chance for a patient suffering from cancer of the breast. Cases of cancer treated only with internal medicines, or external applications, or by dietetic methods are not being effectually treated. This does not mean that such agents as radium and X-rays cannot be usefully employed as aids to surgery, or in cases in which surgical operation is impossible. Unfortunately, with improvement in surgical technique there has been no corresponding increase in the proportion of cases which reach the surgeon at a stage of the disease when such treatment offers the greatest advantage, and this fact has to be remembered in assessing the results of surgical treatment. As to varieties of operation, it is indubitable that the better results obtained at the present time by operation in cancer of the breast mainly depend upon the completeness with which the outlying portions of the cancer are removed. It is satisfactory to note that the modern "complete" operation does not add in any significant degree to the risk of the operation itself, nor to subsequent disability, so far as the patient is concerned. A modern extension of the operation lies in the addition of such advantages as are afforded by radium and X rays, to the "complete operation." The object of this radiation treatment subsequent to operation is to deal with microscopical foci of living cancer cells that may lie beyond the limits of the operation, so as to prevent their development.

Results of Operation.

The most important point of all, from the patient's aspect, is the measure of the success of surgical treatment, and this is very difficult to assess. The *average* duration of life in patients whose disease has followed a natural course is estimated at little more than three years. No precisely comparable figure for patients who have been operated upon can be given owing to the difficulty of keeping in touch with them for perhaps 10, 15, or more years after operation. A majority of surgeons have been obliged to content themselves with reporting the percentages of their patients who have survived three years from the date of operation.

The aggregate results, based on the experience of many surgeons in different countries, are as follows:—When the old and now generally superseded incomplete operation was performed, about 25 per cent. of the patients were known to be alive at the end of three years after operation. When the more complete operation of modern times was performed, twice as many, some 50 per cent., survived three years, and 33 per cent. survived five years after operation. These statistics, however, relate to patients who at the time of operation were in various stages of the disease, some in a condition such that, although the surgeon could be reasonably sure that operation would afford relief, and *might* eradicate the disease altogether, he could have little confidence that the disease would not recur. On the other hand, statistics exist of the results when the disease at the time the patient came to the surgeon appeared to be in an early stage and limited to the breast only. In this early condition it is *certain* that 60 per cent., and highly probable that 75 per cent., of the patients were alive and well three years after operation. Indeed, some experienced surgeons have thought that the percentage of cured patients might, in these circumstances, be stated to reach 75 per cent.

Prolongation of Life.

Upon the basis of all these statistics it is possible to reach an average figure of the duration of life after operation which can be set against the average of some three and a half years in the unoperated cases, but this can only be done by means of assumptions, to state which would require a technical and detailed account unsuited to this memorandum. It may, however, be stated that, even under the unsatisfactory conditions imposed by the late stage at which many cases come under surgical observation, which gravely lowers the average success recorded in the massed statistics, the mean duration of life is prolonged several years. In the special circumstances of operation at the most favourable—that is, the earliest—moment after recognition of a lump in the breast, there is an average prolongation of life amounting to *many* years. The Committee have advisedly refrained from adopting the word "cure" and have only spoken of the prolongation of life. It is, however, certain that cure, in the widest popular sense of the word, has frequently been effected by *early* operation—i.e., that patients have lived 10, 15, 20, or more years and died ultimately of some other disease. The surgeon cannot promise this, however early the operation, but he is entitled to assert that in a great majority of cases life will be considerably prolonged and in a still greater majority rendered more acceptable, freer from pain, and more capable of active enjoyment. On the other hand, the after-history of patients not operated upon, or operated upon when the disease has spread beyond its first point of attack, can be foretold with equal certainty and is a sad one: it will not often exceed three or four years. The teaching of surgical statistics is, then, that the results of early and complete operation justify not a certain, but a highly favourable, prognosis.

---

[1] Cancer.—iii. Circular 496. Ministry of Health, 1924. H.M. Stationery Office. 1*d.* The two preceding pamphlets were dealt with in THE LANCET, 1923, ii., 479; and 1924, i., 770.

A Demand for Local Inquiries.

The considerations set out in the memorandum suggest that local inquiries may be useful to ascertain the extent to which, in a given area, cancer of the breast is now being allowed to continue to a fatal termination without appropriate surgical treatment. It is suggested that local authorities, in conjunction with local representative bodies of the medical profession in suitable areas, might periodically undertake a review of such questions as this as well as of the facilities given locally (1) for clinical consultations and for pathological examinations, and (2) for the treatment, especially operative treatment, of cases of cancer.

IMPERIAL SOCIAL HYGIENE CONGRESS AT WEMBLEY, MAY 12TH–16TH.

(*Concluded from p. 1024.*)

THE proceedings of this congress, the first day of which was reported in our columns last week, demonstrated the many-sidedness of the problem and the existence of a large body of men and women, lay and medical, keenly interested in its solution. Important papers were read on a number of more or less closely related topics. It may be useful to summarise here some of the points in the control of venereal diseases on which there appear to be general agreement and also those which give rise to controversy.

Education.

Agreement was general that much more needs to be done to educate the public as to the serious ravages of these diseases, that cure is a means of prevention, that early treatment is essential to cure, and that the attainment of a higher moral standard and the avoidance of promiscuous sexual intercourse should be put in the forefront. Education of the young and adolescents in sex hygiene, it was pointed out, should be founded on the teaching of self-control, beginning in infancy, and on education in biology and good citizenship from the elementary school period onwards. Sir Frederick Mott's interesting paper showed how necessary it is for elders to understand and allow for the varying effects of the critical period of puberty on the adolescent of either sex. In some quarters it was contended that health authorities are not sufficiently interested, owing to the fact that they have been, as it were, "contracted out" of the schemes, and have not that direct interest in the suppression of this section of infectious diseases, which is, perhaps, more important than any other to the health of the community. The old idea that venereal diseases are a just punishment for immorality is evidently not dead, in spite of the well-known fact that a large proportion of the sufferers acquire the disease innocently, and it was stated that some institutions still regard these patients as pariahs. Evidently the truth that, in these diseases particularly, adequate treatment is a measure of prevention of first-class importance, must be insisted upon day in and day out. The obvious corollary is that, in order to get the sick treated, every facility and a sympathetic reception must be provided at all clinics and institutions engaged in the work.

Efficiency of the V.D. Clinics.

It was made evident by the papers and discussion on May 14th that the clinics at present fail to secure the attendance of a large proportion of those who need treatment, and that of those who do attend a considerable proportion default. Sir George Newman suggested that the amount of default is exaggerated by the high standard of cure adopted, and that in many cases those not returned as cured have been, no doubt, rendered permanently non-infective or greatly relieved. On the other hand, Mr. David Lees, of Edinburgh, and Colonel L. W. Harrison (Ministry of Health) were of opinion that the clinics with the highest standard of cure showed the smallest proportion of defaulters. Mr. Lees considered that one of the main factors in reducing the failure to continue treatment at the Edinburgh clinic from 40 per cent. four years ago to the present low figure of 14½ per cent. had been the discouragement of self-treatment. Patients who are instructed to treat themselves are apt to cease attending. All patients at the Edinburgh clinic are required to attend weekly or fortnightly, and treatment is, as far as possible, administered at the clinic. Colonel Harrison emphasised the great advantage of clinics open all day (say from 8 A.M. till 10 P.M.) over clinics open only at stated hours, and compared the results of one all-and-every-day clinic with a percentage of "ceased attendance" of 12·3 for syphilis and 14·6 for gonorrhœa, with the results of a clinic open at restricted hours with a percentage of "ceased attendance" of 33·2 for syphilis and 32·4 for gonorrhœa. Colonel Harrison also insisted upon the need for setting aside time for the systematic and thorough examination of the cases of chronic gonorrhœa. If this were not done, and the treatment of such cases became merely routine, the patients would lose hope and cease to attend. There was general agreement that the tact and sympathy of the medical officer was a most powerful factor in reducing default to a minimum. Dr. F. N. Kay Menzies would like to have the 28 London centres reduced in number to six or eight thoroughly efficient all-day clinics. It is quite clear that a large number of the clinics do not approach the high standard laid down by Colonel Harrison and Dr. Lees, and that apart from the question of patients ceasing to attend before cure is completed, a large number of cases do not come up for treatment at all. More cases of gonorrhœa attend than formerly, but a very large proportion of female gonorrhœa goes untreated. Very little syphilis of parturient women is treated. Hostels are needed to ensure the successful treatment of single girls who are in domestic service or other employment. Special sessions are needed for married women and children, although the all-day clinic minimises the objections to the herding together of all types of patients in the common waiting-room. The looking-up of contacts and infecting cases is a difficult matter. Colonel Harrison pointed out how much could be done in this respect by tactful almoners, and would like to see an almoner attached to each clinic. Miss Frances Brown (supervisor of the Venereal Disease Nursing Department of Public Health, Toronto, Canada) showed that in Canada each V.D. clinic receiving a Government grant is required to employ a public health nurse, and that on this nurse devolve the duties of (1) securing the regular attendance of patients; (2) securing the examination of other members of the family; and (3) instructing the family as to home treatment. It was evident from the papers and discussion that little has as yet been done in this country in the way of searching out contacts and securing their treatment, and that the discovery of cases of congenital syphilis, vulvo-vaginitis, and ophthalmia neonatorum rarely leads up to the treatment of the parents, infective cases, or contacts.

The Place of the Local Authority.

Scotland has evidently made up its mind that some scheme of notification with a view to securing the continuous treatment of sufferers is necessary. Even Mr. Lees, in whose clinic default is now so small, thinks some system of control is necessary to enable us to deal with patients who are irresponsive to the most skilled persuasive powers, with suspected and known sources of infection, and with known sources and cases of hereditary disease. He favours a system of confidential notification and compulsory continuous treatment, such as that in force in Canada. Dr. A. K. Chalmers thought schemes should be carried out directly by the local authorities, and said there was a growing feeling that we were not getting the best results from the large expenditure involved. Dr. W. A. Daley (Blackburn) favoured an experiment in notification and the treatment of women and children at maternity and child welfare centres. Dr. R. F. M. Picken (Cardiff) said it was difficult to get health committees really interested as long as they were contracted out of the schemes. Judge Harvey (convener of the Edinburgh Health Committee) said that 27 recalcitrant authorities in Scotland which had not yet adopted schemes should be pressed, and mentioned that no proper treatment had yet been adopted in prisons in Scotland. Sir Henry Keith mentioned that the Convention of Scottish Burghs has passed a resolution in favour of notification. Many speakers with experience of treatment drew attention to one great advantage from having the V.D. clinics at general hospitals—namely, that the syphilologist thus readily secures the consultative assistance of the ophthalmologist, dermatologist, neurologist, &c. Colonel Harrison thought that at the present time the improvement of facilities at the clinics was much more pressing than the consideration of compulsory notification or treatment. Dr. Letitia Fairfield produced evidence that more of the gonorrhœa cases were seeking treatment at the clinics. The work of the lady almoner was invaluable. She was able to follow up clues and get contacts, not by asking questions but by listening, in her capacity as booking clerk, to the stories of patients who appealed for her help. In London they were opposed to notification. Improved treatment was wanted for all gynæcological ailments and the married working class woman had too low a standard of health.

The Position of the General Practitioner.

The treatment of both gonorrhœa and syphilis has become so highly technical that it is obvious that general practitioners who desire to carry out the treatment will have to specially qualify themselves. If they have done so, the treatment of patients will make such demands on their time that it is difficult to see how they can receive adequate financial compensation from the patients themselves. Where a V.D. centre, as in the case of Edinburgh, serves a large area, Mr. Lees favoured the establishment of local subcentres under the direction of the principal centre, where daily and intermediate treatment can be carried out. At such subcentres panels of general practitioners could possibly work, with the advantage of being able to consult with the specialist at the centre. The family doctor's coöperation must be obtained. Under present circumstances he should be invaluable in securing the treatment of contacts and infecting cases in the family. The need for clerical assistance being provided at each clinic was emphasised during the discussions, in order that each general practitioner may receive full particulars with regard to each patient sent by him to the clinic. The possibilities of "team" work were mentioned by which one general practitioner, specially trained, could undertake V.D. treatment for his neighbours.

Imperial Questions.

The last day of the Congress was devoted to the discussion of problems in the prevention and treatment of V.D. in the various parts of the Empire. Mr. L. S. Amery, M.P., president of the section, said the problems in the Dominions were not essentially different from those in this country, but that the interchange of ideas and experiences would add to the common stock of knowledge and efficiency. In the discussion the work which is being carried out in Canada, Australia, India, South, East, and West Africa, and the West Indies came under review and the Congress concluded with a discussion on propaganda among illiterate races.

To those who feel discouraged by the smallness of the results when compared with the immensity of the problem we commend the cheery dictum of Dr. Margaret Rorke: "We have made great strides in the last seven years; in another ten we shall work wonders."

THE NEW NATURAL BATHS AT BUXTON.

The Opening Ceremony.

On the afternoon of Saturday, May 17th, the new natural baths at Buxton were formally opened by Sir Humphry Rolleston. The ceremony was performed in fine weather before a large assembly of townsfolk and visitors, and, as guests of the corporation, there were gathered representatives of the medical profession from all parts of the country. The platform party included the Duke of Devonshire, Lord Hartington, M.P., the mayors of several towns, and local civic dignitaries. The Mayor of Buxton, Mr. G. Smithurst, in welcoming Sir Humphry Rolleston, said they had always regarded their ownership of the springs in Buxton as a national trust as well as a local asset. Dr. T. H. Cooper, Chairman of the Baths Committee, together with the architect and the contractor of the new structure, were presented to Sir Humphry Rolleston, who then performed the opening rite. He said:—

"The very few words that are necessary to declare open the new natural mineral-water baths must begin with what is uppermost in our minds—namely, sincere congratulations to the corporation on their wisdom in initiating and so satisfactorily carrying through this great undertaking. This progressive policy, though no doubt in these times not without its attendant anxieties, is the true road to success, and, further, the corporation has made success the more certain by asking the medical profession for their advice, and by taking the somewhat rare and original course of following it. Though with great natural advantages in its healthy and beautiful surroundings, Buxton has done right in making every endeavour to utilise the outstanding properties of its waters by the most complete installation of balneological appliances. Further, the corporation is to be congratulated on realising the importance of continually breaking fresh ground—of making new knowledge, and of putting this into practice by subsidising the research laboratories at the Devonshire Hospital. From a medical point of view this is of paramount importance, for there is still a great deal to learn about the diseases which patients come to Buxton to have cured on the one hand, and about the method of action of the waters on these diseases on the other hand.

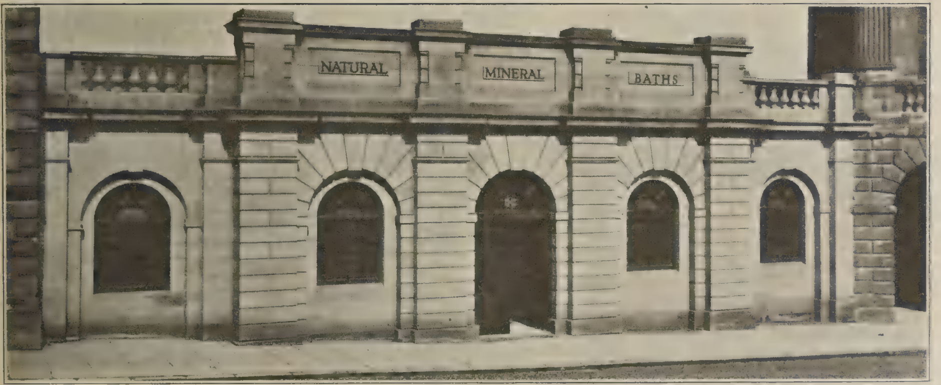
"The new mineral baths, which I now have the honour to declare open, therefore start on their career with the best auguries—namely, a scientific in place of the old empirical basis of treatment. Thus they deserve, as we may confidently believe they will achieve, high success."

Inspection of the Baths.

A vote of thanks to Sir Humphry Rolleston having been proposed by the Duke of Devonshire, a tour of inspection of the baths was then made. These baths are termed "natural" because in the case of swimming and immersion baths the water is continually flowing through them and the patient is thus immersed in a stream of running water as in the more primitive forms, where the patients bathe in a pool or lake at the source of the spring. The new building is contiguous to the south end of the famous crescent and is designed in harmony with its surroundings. A lounge panelled in oak leads to the swimming pools, which are three in number, two for men and one for ladies. The largest is 30 ft. long by 18 ft. wide, and is situated over one of the principal springs, the water from which enters the bath through perforated marble slabs which are placed on the surface of the rock. The blue colour of the water is shown up by the white marble and tiling, and large bubbles of gas rise continuously to the surface. The ladies' bathing pool is similarly planned, with perhaps special attention to those refinements which add not a little to the success of the cure.

The springs of Buxton are of two kinds: the radio-active thermal water, upon which the fame of Buxton throughout has been based, and the chalybeate spring. The thermal water emerges from the limestone rock, which forms one of the geological features of the district, by nine springs which are undoubtedly outlets from the same subterranean reservoir, as they are identical in temperature and composition and rise within a radius of a few yards. From one of these springs alone about 2,000,000 litres flow daily at a uniform temperature of 82° F. The gas with which the water is impregnated consists chiefly of nitrogen and CO_2, but contains argon, helium, neon, and other elements. The temperature of the swimming bath, at 82° F., is thus pleasant and stimulating. In addition to the swimming pools a new bath has been devised and installed in which the water is warmed to 90° F. by means of a special calorifier while still running continuously through the bath, thus retaining its natural character of running water and losing none of its gases or radio-activity. A further addition to this bath, which is also in use in the hot baths, is an apparatus by which compressed air can be forced through the water setting up a strong effervescence. It is anticipated that this new method will prove a most valuable addition to the modes of treatment already in use. Among the chief improvements and additions which have been made since the principle of heating water was adopted have been the undercurrent douche and the Buxton system of douche massage.

FIG. 1.

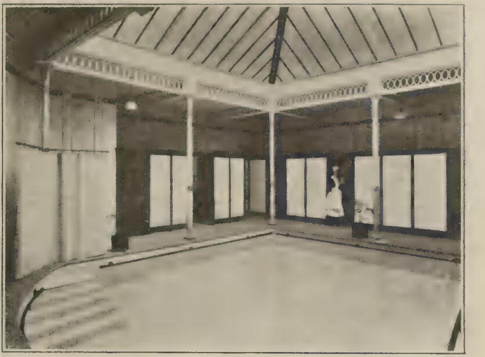


The New Baths, Buxton. [*Photos by Hunters, Buxton.*

The Devonshire Hospital.

Following the inspection of the baths and St. Ann's Well, one of the principal springs, where the waters may be drunk in comfort, tea was provided for the guests in the Buxton gardens. This was followed by a visit to the Devonshire Hospital, which claims to be the largest hospital for rheumatic disease in the world, with 300 beds and an out-patient department. It is in the laboratory of the Devonshire Hospital that research is being carried out as to the properties and effects of the Buxton waters both in their external and in their internal application.

FIG. 2.



Ladies' Swimming Bath.

The Banquet.

In the evening a banquet was given by the corporation at the Palace Hotel. Over 130 guests were present and of these about 100 were medical men. Responding to the toast of his health, Sir Humphry Rolleston said:—

"Among health resorts a distinction should perhaps be more definitely drawn between: (1) Those benefiting the visitors in a general manner on account of the climatic conditions, pure air and water, altitude, atmospheric temperature and composition, winds, sun, and other factors; and (2) spas which in addition exert a specific action on the visitors in virtue of the effects of the external and internal use of waters, and of the utilisation of active principles contained in the water.

"1. That a change of environment exerts an influence is a commonplace; thus improvement in health may follow a visit either to a health resort without any special baths or waters, or to a spa where no real use is made of the special advantages that it possesses. The study of the effects due to such a change comes under the heading of medical climatology, but that climatology and hydrology should be closely connected is too obvious to require argument. A regulated life, supervised diet and exercise, and freedom from worry are no doubt more easily ensured at a health resort than at home, and in some instances the good effects of a visit to a health resort are thus explained; in the past spas were often used as pleasant places for an irresponsible holiday after a busy season or life in town without any serious attention to the special requirements of the individual visitor, or to the peculiar properties of the spa treatment. Where and when this spirit exists and as long as the tide of fashion is sufficient to keep the resort full, there is a danger that the special properties of the waters and the best methods of applying them will be neglected, for the demand controls the supply, and scientific investigation receives no encouragement and less stimulus. The bathing establishments, if there are any, are not kept up to date, and their value and use even as a window-dressing attraction will dwindle progressively. Buxton is in no way open to any reproach on these scores, and while far from relying on them alone has great natural advantages from its altitude (1000 ft.) and beautiful surroundings; it has much historical interest, sharing with Bath the imprimatur of Roman patronage. These are most important accessories, for it would be a grave mistake to neglect the psychological factor of inspiring a helpful *joie de vivre* among those who come for a cure, and thus to obviate the boredom that a search for health and relief from pain may bring in its train. Cheerful and attractive surroundings and pleasing distractions have their proper place in a cure, and it must be admitted that, in the past at least, British health resorts have lagged behind many on the continent. But this handicap is rapidly being eliminated.

"2. The second category of health resorts is that of the spas with their medicinal waters and careful medical supervision—two factors inseparable for success. Spas, such as Buxton, Bath, and Harrogate, are, as Dr. Fortescue Fox, our leader in hydrology, has insisted, a national asset. But their value must depend on skilled control of the patients, and circumstances are not always and everywhere favourable to the fulfilment of this necessary condition. Directions as to diet and treatment may be given but not faithfully followed, and it is not surprising that such 'a cure' brings disappointment. An obvious remedy against dietetic lapses is to remove temptation, so that patients undergoing a cure should find it impossible at their hotels to go outside their prescribed dietary, both as regards quality and perhaps even the more difficult question of quantity. The British spas have their special characters, and the tonic ones, such as Buxton, need fear no rivals in their natural advantages; but to render these fully available an up-to-date and complete installation, such as is being opened here to-day, is necessary. In addition to the baths and other appliances for hydrological treatment and to all that is included under physiotherapy, such as massage, exercises, and electricity, an important department is that for the diagnosis and controlled treatment of disease; the poor and those of limited means can be cared for in the mineral-water hospitals, such as the Devonshire Hospital here, with its 300 beds and clinical laboratories; but for the well-to-do, as is perhaps in keeping with our characteristics of national individualism and freedom, there are only hotels, pensions, and lodgings with practically complete liberty of action and varying degrees of luxury. Should not these unconsciously unfortunates have equal advantages with the poorer sufferers and have the opportunity of going into hostels or nursing homes with all the advantages of an up-to-date clinic?

The Importance of Research Work.

"Clinical and biochemical laboratories, such as are attached to the Devonshire Hospital, are essential not only for the accurate diagnosis of the diseases of individual patients but for the maintenance and advance of the science of hydrology and physiotherapy. These methods of treatment, which are so closely allied to the *vis medicatrix naturæ*, have in the course of their long existence passed from an early semi-religious and superstitious period, through a long empirical phase, into the scientific era which began about half a century ago. A good deal of investigation has been started especially since, and because of the stimulus of the war, but the science of hydrology is still in an early stage of development. Of the physiological effects of water internally and externally there is an enormous amount to be learnt, and the profession naturally looks to its members with the opportunities at their hand to take a leading share in the advance of hydrology. This has been fully recognised by British leaders in hydrology, and their exertions are shown in the young and energetic *Archives of Medical Hydrology*. The future of scientific medical hydrology, and so the lasting and genuine success of spas, depends on research, and it is desirable to emphasise the principle that the only real advertisement of a spa is the publication of good research work into the properties—chemical, biological, and therapeutical—of the waters and into the diseases which can be beneficially treated thereby. It is to their honour that the municipality of Buxton have recognised the value of such work and have contributed to the salary of the analytical chemist attached to the research laboratory of the Devonshire Hospital."

"The Prosperity of Buxton" was proposed by the Duke of Devonshire, who said that people talked in these days about the key industries; he thought the key of all industries was health. Buxton, he said, had made a real contribution to the subject. In reply to the toast of "The Guests," proposed by Alderman C. W. Buckley, M.D., Sir W. H. Willcox and Dr. R. A. Fleming responded.

The guests included the Duke of Devonshire, Lord Hartington, the Lord Mayor of Sheffield, the Mayors of Salford, Bath, Stockport, Derby, Ilkeston, Macclesfield, and Leamington, the Rev. J. Stainer Wilkinson, Sir W. H. Willcox, Dr. G. Newton Pitt, Sir J. W. Moore, Canon Scott-Moncrieff, Sir W. J. Thompson, Dr. H. R. Spencer, Dr. F. J. Poynton, Dr. R. A. Fleming, Dr. R. Fortescue Fox, Sir James Barr, Dr. W. J. Tyson, Mr. A. R. Courtenay, Dr. J. D. Stanley, Dr. E. P. Poulton, Dr. W. Edgecombe, Dr. Langdon Brown, Dr. C. Wilson, Dr. J. S. Bury, Dr. A. G. Gibson, and Alderman T. H. Cooper.

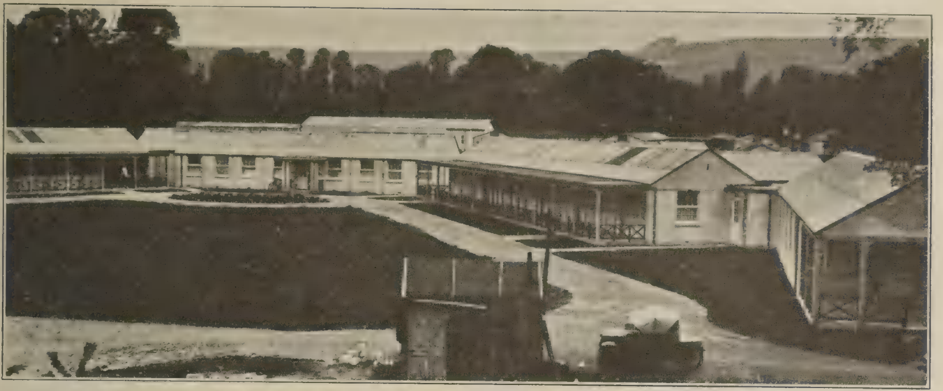
On the following day the guests were entertained to luncheon at the Buxton Hydropathic, and were taken for drives through the picturesque Peak District by the corporation.

ROYAL UNITED HOSPITAL, BATH.

OPENING OF PRIVATE AND ORTHOPÆDIC WARDS.

ON May 16th an extension of the Royal United Hospital, Bath, was formally opened by the Duke of Connaught, who was welcomed by Lieut.-Colonel E. Lewis, deputy chairman of the Royal United Hospital, acting for Sir Percy Stothert, chairman, who was unavoidably absent through illness. The Royal United Hospital was formed in 1826 by the amalgamation of two hospitals, and in 1866 a new wing was added as a memorial to Prince Albert. The hospital, which serves the city of Bath and an area of 20 miles round, occupies a site in the city which does not allow of any further extension. A scheme for an

Fig. 1.



Royal United Hospital, Bath. General View of the Private Wards.

[*Photos by permission of "Bath Herald."*

Fig. 2.

Interior of a Ward (12 Beds).

extension on a new site, and provision of paying wards for persons of moderate means, was placed before the managing board in 1920 by certain members of the staff of the hospital, the suggested site being the land at Combe Park on which the Bath War Hospital was built in 1915. This scheme was subsequently adopted at a public meeting in the Guildhall, Bath. The site at Combe Park, consisting of about 20 acres, was purchased, a portion being retained and the remainder leased to the Pensions Ministry, which had taken over the war hospital. On the portion retained, the private hospital and an orthopædic hospital for the treatment of surgical tuberculosis in children have been erected. The private hospital is a one-storey building with a total accommodation of 72 beds. In the admission of patients preference will be given to those from Bath and the area covered by the Royal United Hospital, but others will be admitted provided there are beds available. All patients can be attended by their own doctors.

About 100 yards to the north of the private hospital is the orthopædic ward, consisting of one large open-air room about 80 feet long and 30 feet wide, giving accommodation for the reception of 37 patients. The ward faces due south and is open in its entire length, but has a sun balcony in front of it partially covered by a lean-to glass roof. The surgical staff consists of members of the staff of the Royal United Hospital, and there is a specially trained nursing staff. In accordance with the requirements of the Board of Education, children while undergoing treatment in hospital will be educated by a fully qualified schoolmistress.

It is proposed that this shall be the central unit of an organisation covering the area served by the Royal United Hospital in parts of Somerset, Wiltshire, and Gloucestershire, on the lines of the Wingfield and Shropshire Orthopædic Hospitals, and local clinics will be established at suitable centres throughout the area at which will be carried out outpatient treatment, periodical inspection of all outside cases, the examination and diagnosis of new cases. A specially trained orthopædic after-care sister from the central hospital will visit them regularly, and members of the surgical staff of the hospital will attend at stated intervals. These clinics will be controlled by local committees in coöperation with the medical men practising in their neighbourhood.

On Wednesday, May 28th, a meeting will be held at the hospital by the Bath Division of the British Medical Association, which will be in the nature of an official medical opening of the new wards. These will be open for inspection, and Lord Dawson of Penn will deliver an address.

UNITED STATES OF AMERICA.

(From an Occasional Correspondent.)

Cyanogen Chloride for Fumigation.

Since the introduction of cyanogen as a fumigating agent on board ships several fatal accidents have been reported from various parts of the world, so that it became evident that either a very valuable disinfectant—fatal in comparatively low concentration both to insects and vermin yet comparatively non-injurious to cargo—must either be abandoned or else improved precautionary measures must be introduced. The United States Public Health Service has been experimenting with the latter object in view and during the last year has elaborated a chemical safeguard which has so far given most satisfactory results. It consists in combining the cyanogen with chlorine so that the poisonous fumes may give urgent warning of their presence. Cyanogen chloride is said to be produced by a chemical reaction which is expressed as follows :—

$$3\ NaCN + NaClO_3 + 6\ HCl = 4\ NaCl + 3\ H_2O + 3\ CNCl.$$

The following prescription furnishes sufficient gas for the fumigation of 1000 cubic feet:—

Sodium cyanide	℥iv.	Hydrochloric acid ..	℥xvii.
Sodium chlorate	℥ii.	Water	℥xvii.

During the last nine months this gas has been used as a routine at the port of Baltimore quarantine station. On two occasions stowaways have escaped the vigilance and warning cries of those sent down to clear the hold—on one occasion the man said that he was asleep in his hiding place, and on the other he escaped without being noticed to the deck, where he hid in a coil of rope. Both men were driven off the ship by the "tear-gas" action of the new compound before the cyanide action had time to cause any serious injury. It is found, too, that by the time the former action is lost through dilution, the latter has also disappeared.

I understand that the only reason which has prevented the Public Health Service from publishing this discovery is its natural anxiety to give the method a thorough trial and to perfect the technique. It was found at Baltimore, for example, that there is danger of causing fire through the excessive heat developed in the chemical reaction, and that this danger could be obviated by first dissolving the sodium chlorate in water, so that those making the mixture are obliged to dilute the final solution to a certain degree. I had the privilege of witnessing a demonstration, and noticed the bright yellow fumes of cyanogen chloride and the very marked irritant effect on the mucous membranes of those who were imprudent enough to sample even a small and well-diluted dose.

Automobile Accidents in 1923.

Estimates issued by the National Bureau of Casualty and Surety Underwriters indicate that the 1922 record number of fatal automobile accidents has been exceeded by some 2000 deaths in 1923. Accidents occurring at level crossings are still a common source of fatalities, despite the terrifying pictures exhibited at all railway stations showing with vivid realism the immediate preliminaries to such a disaster. These accidents included, the total amounts to more than 17,000 deaths. Roughly, one-third of the slain were children under 15 years of age.

Tuberculosis Research at Johns Hopkins Hospital.

A great deal of work on the nature of infection and the development of immunity in tuberculosis has been carried out in recent years at Johns Hopkins. The results have not been spectacular, but on the other hand a foundation is being laid, a foundation of fundamental knowledge derived from carefully controlled animal experimentation which is certain to prove of great value to tuberculosis research everywhere. Much of this work has been published in your columns. In giving their report this week of the "work in progress in the Kenneth Dows Tuberculosis Laboratory" Dr. A. K. Krause and Dr. H. S. Willis reminded the Medical Society of Johns Hopkins Hospital of the important distinction to be drawn between tuberculosis in the guinea-pig and in the rabbit. The former shows pathological changes associated with the absence of lymphatic tissue in the parenchyma of the lung and its abundance at the hilum, the latter a pulmonary type of tuberculosis associated with lymphatic deposits at every bifurcation of the bronchial tree with atrophied glands at the hilum. The experimental guinea-pig thus corresponds very closely with the infected human child, the experimental rabbit anatomically and clinically reproduces the human adult.

The recent work hitherto unpublished includes experiments to determine the rate of migration of infecting bacilli in normal and in allergic pigs. An intradermal dose of living bacilli was given to young guinea-pigs and their migration controlled (1) by removal of an area of skin for 15-18 mm. around the point of inoculation at varying intervals after the injection; (2) by removal of the neighbouring lymphatic nodes at varying intervals and examination of same for bacilli. The experimenters were surprised at the rapidity with which the bacilli found their way in normal animals to a distance from the point of injection into the skin. Within four hours (in one case within a single hour) they had traversed the area of skin excised. It took from 10 to 24 hours to reach the nearest lymphatic gland. In allergic animals, on the other hand, the time was very greatly increased. Three to four days were needed to traverse the area of excised skin and as much as two to three weeks to reach the nearest lymph-nodes. Another set of experiments was designed to determine whether continuous reinfection with sub-lethal doses could bring about a progressive and fatal tuberculosis. The R1 strain—an avirulent bacillus originally isolated by Dr. Trudeau at Saranac Lake—was selected for this experiment. It was found that 86 daily intradermal injections did not have this effect, only a slight depression of allergy resulted. A second batch of animals given daily inoculations were killed on the sixty-ninth day. Although there were multiple subcutaneous abscesses no visceral tuberculosis was observed. However, the interesting observation was made that all the serous membranes were covered with adhesive exudate. This phenomenon Dr. Krause does not explain—he proposes to investigate it further. Again, a third batch of animals were given daily inoculations for from 30 to 50 days and then inoculated with a virulent germ. Comparison with controls (normal animals and animals inoculated with a single dose of R 1) indicated that the immunity had been lowered to some extent by the series of inoculations.

I understand that the whole series of experiments are to be reported in detail in a forthcoming number of the American *Review of Tuberculosis.*

INFECTIOUS DISEASES IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 10TH, 1924.

Notifications.—The following cases of infectious disease were notified during the week—namely: Small-pox, 82; scarlet fever, 1420; diphtheria, 627; enteric fever, 65; pneumonia, 1011; puerperal fever, 29; cerebro-spinal fever, 9; acute poliomyelitis, 6; acute polioencephalitis, 2; encephalitis lethargica, 290; dysentery, 2; ophthalmia neonatorum, 119. No cases of cholera, plague, or typhus fever were notified. The cases of encephalitis lethargica showed an increase on the figure 278 of the previous week.

Deaths.—In the aggregate of great towns the deaths from influenza fell further from 167 to 95. In London the deaths from diphtheria fell to 7, those from measles to 22, while the deaths from influenza numbered only 11.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Act. Surgeon Lts. (D) to be Surgeon Lts. (D): E. R. Longhurst, M. V. Barnes, C. J. Barrable, D. L. Simpson, and D. H. Le Marchant.

ROYAL ARMY MEDICAL CORPS.

Capt. G. Fleming retires receiving a gratuity.

ROYAL ARMY MEDICAL COLLEGE.

Maj. G. De la Cour, R.A.M.C., to be Professor, vice Lt.-Col. and Bt. Col. J. W. West, K.H.S., R.A.M.C.

TERRITORIAL ARMY.

E. L. Elliott (late Royal Navy) to be Capt.

J. C. Adam and C. Stewart to be Lts.

ROYAL AIR FORCE.

Flight Lt. W. D. Miller is transferred to the Reserve, Class D.2.

DEATHS IN THE SERVICES.

Deputy Inspector-General Archibald McKinlay, R.N., retired, who died on May 17th at Southsea, qualified as L.R.C.S.I. in 1872 and as L.R.C.P.I. in the following year, entered the Royal Navy as a surgeon in 1874, and was subsequently appointed to the *Nymphe* in Australia. In 1880 he joined the gunboat *Mosquito* in China, and saw active service in this vessel during the Egyptian War of 1882 (Egyptian medal and Khedive's bronze star). He was promoted to staff surgeon in 1886, and fleet surgeon in 1891. He retired in 1905.

Correspondence.

"Audi alteram partem."

THE MANCHESTER RADIUM INSTITUTE.

To the Editor of THE LANCET.

SIR,—The annotation in your current issue on the last annual report of the Manchester and District Radium Institute raises one or two points and omits others. For instance, it quotes the fact that 64 cases of malignant disease were rendered free from symptoms and signs of disease during the year, saying at the same time that the result is satisfactory enough as far as it goes, but many of these cases can only have been treated within a few months of writing the report, and the question of permanent benefit must be judged after a longer interval of time. This statement is obviously perfectly correct, but as a criticism it is not so good. Every year an annual report has to make a statement of what has been going on during the year. Therefore this quotation of 64 cases is merely that and nothing more. If any claim at all were to be made it would be merely that they were 64 examples of supremely good palliation. As a matter of fact, in a report of an institute such as the Manchester and District Radium Institute, one report alone cannot be regarded as an entity entirely separated from its fellows. In the year 1921, 2500 cases were reported upon, 1753 of which were malignant, none of which had been treated during the two years or more immediately preceding the report. The period dealt with was one of five years—viz., from 1915 to 1919 inclusive. I think it is only fair that those figures alone should be taken as a reasoned statement of what may be expected from radium treatment over a prolonged period.

Practically every year a smaller branch of the subject is dealt with, as it is manifestly impossible to go to the tremendous labour of dealing with thousands of cases each year in the report. In the report for the year 1923, for instance, carcinoma of the body of the uterus is dealt with in detail over a period of years, also cases of uterine hæmorrhage from various causes. In these cases the figures give an idea of what may ultimately be expected in radium treatment of these conditions. In the present report (for 1923) details of technique are given specifically in the case of carcinoma of the body of the uterus and uterine hæmorrhage, which are dealt with at length. It cannot be expected that each report will be a text-book, or part of a text-book, on radium treatment. As long ago as 1919 the technique of the use of unscreened tubes in the treatment of carcinoma of the mouth was given. The technique is perfectly simple and remains almost the same. The only thing being that now it seems to be firmly established that one millicurie of emanation in an unscreened glass tube left in a tumour indefinitely can be placed in each cubic centimetre of growth safely.

I do not regard the term "seeds" as being scientific. It is used in parts of the United States, although one of the most experienced radiologists there does not use the expression, but calls them "active points," while in the reports of the Manchester and District Radium Institute they are referred to consistently each year as unscreened tubes. This method of treatment of carcinoma of the mouth, and for that matter epithelioma of the vulva, is very satisfactory, and for that reason has been persevered with in Manchester. So far we have not used the French method of burying very small, screened quantities of radium in tumours of the mouth for long periods. I have not had the opportunity of personally seeing it done, and would rather do so before adopting a technique which, so far as I can hear, does not promise results better than those obtained from the use of unscreened tubes. With regard to the criticism of the treatment of cases of carcinoma of the breast, the statement concerning the use of diathermy is purely preliminary, and it does not seem justifiable at this stage to give too definite details as to the technique. The burying of emanation tubes along the course of the lymphatics is a perfectly simple procedure, and it needs nothing but a little practice. This procedure was dealt with in the report of the year 1916.

I feel that any critic of a report such as that of the Manchester and District Radium Institute should acquaint himself with what has already been written in the previous reports, and consider it merely as one of a series.

I am, Sir, yours faithfully,
May 19th, 1924. ARTHUR BURROWS.

BATHING AND EAR DISEASE.

To the Editor of THE LANCET.

SIR,—Now that the bathing season is about to commence, there is one question which might well be considered—namely, is it desirable in apparently healthy children to take precautions to prevent the entrance of water into the ears? The aural surgeons whom I have asked say that it is. Further, Milligan and Wingrave, in their "Diseases of the Ear" (p. 18), give among the causes of ear disease "the entrance of cold water into the external meatus, as in bathing and diving," and, indeed, it is easy to see how a breaking wave may cause inflammation of the membrana to be followed by middle-ear disease and deafness.

Valuable suggestions may be gained from nature. The seals, which are carnivorous mammals adapted for an amphibious life, have no external ears. In them "the auditory nerve is very large, and though the auricular aperture is closed by a mechanism somewhat similar to that which shuts the nostrils in order to protect the internal parts of the organ from the consequences of the great pressure of the water when the animal is in the deeps, it is evident that seals hear very well under water."[1] In his "Physiology" (1867, vol. i., p. 522) Marshall tells us that in the water-shrew the ear is provided with a valve-like antitragus, to prevent the entrance of water into the ear when diving.

When one considers how serious is ear disease, and how easily the entrance of water can be prevented, either with a pad of non-absorbent wool or the wearing of a rubber cap with ear flaps, it would seem that the precautions are worth while.

I am, Sir, yours faithfully,
WALTER EDMUNDS.
Carlton-road, Putney, S.W, May 15th, 1924.

THE PSYCHOLOGY OF VERTIGO.

To the Editor of THE LANCET.

SIR,—As you say in your leading article of May 10th, Dr. W. F. Menzies has succeeded in raising a problem of considerable interest, by drawing attention to the fact that vertigo may be of psychical origin, but his laudable desire to correlate mental with physical phenomena has prevented him from going far enough —psychologically. Dr. Menzies mentions that vertigo is accompanied by a fear of falling; but I agree with you, Sir, when you state that fear is not necessarily an accompaniment of vertigo. Nevertheless, it occurs invariably in association with vertigo of purely psychical origin. In anxiety states the fear of falling, with or without vertigo, is extremely common; the presence or absence of vertigo being dependent merely on the intensity of the fear.

Medical psychologists who have analysed this fear have discovered that it owes its origin to the repression of a desire "to fall" symbolically—i.e., in a moral sense. We find that the same symbolism applies to the falling dream and to hallucinations of falling in psychotic cases, these being the disguised fulfilment of an unconscious wish to fall *morally*. It occurs in anxiety states because the unconscious wish is strong enough to escape the repressing forces in symbolic guise; in other conditions it is due to weakening of the repressing forces. Now, in mental disease of toxic or organic origin, such as acute confusional insanity or general paralysis, the effect of the damage to the cerebral cortex is to weaken the repressing forces, the moral, social, ethical, and conventional instincts, the ego instincts as they have been called; the unconscious thus obtains an opportunity for self-expression and the unconscious *desire* to fall becomes represented in consciousness by its opposite—*fear* of falling—with or without vertigo.

---

[1] Knight's Cyclopædia of Natural History, 1856.

The reason why the symptom, when present in the early stages of general paralysis, disappears later is that in advanced general paralysis the patient's repression is completely destroyed, and he then fully realises his formerly unconscious, but now conscious, wishes by, for example, delusionally possessing thousands of concubines and impregnating the lot every night of his life. My contention is that the semicircular canals have nothing whatever to do with this kind of vertigo.

May I add that giddiness or fear of falling when standing on a height arises in yet another way. It is always traceable (in my experience) to one or more forgotten height incidents in early childhood, usually about the end of the first year of life. Probably the patient has not reached emotionally to the situation at the time; but as soon as it is revived in his memory he is cured of the fear. The psychology of sea-sickness, to which Dr. Menzies also alludes, is yet another story. Medical psychologists are familiar with dozens of ways in which patients associate the sea with their mother—in other words, the sea is a mother symbol. For our present purpose we need only refer to one of these associations—viz., the respiratory rise and fall of the mother's breast while the child is taking food. The rise and fall of a boat during a sea voyage tends to remind certain people of this forgotten situation in an unconscious way, and sea-sickness with its rejection of food is a mode of repressing this infantile memory.

I must not occupy more space by confirmatory details; I only wish to offer a hint that some forms of vertigo are due to purely mental mechanisms, having no relationship with the semicircular canals.

I am, Sir, yours faithfully,
W. H. B. Stoddart.
Cavendish-square, W., May 17th 1924.

POINTS IN THE ADMINISTRATION OF INSULIN.

To the Editor of The Lancet.

Sir,—The discomfort arising from the injection of insulin may be considered under three headings: (1) the prick of the needle, (2) the sensation of stinging following the injection, (3) the inflammatory reaction developing hours later.

(1) The discomfort due to the prick of the needle is almost negligible if the injection be given by a skilled individual and the needle be sharp and polished. If the patient give himself the injection it may be of advantage for him to be acquainted with the fact that some spots in the skin are more sensitive to pain than others. Occasionally the point of the needle is placed upon a pain spot and very considerable discomfort is felt on pressing the needle into the skin. Moving the point a very little may save much pain.

(2) The stinging sensation following immediately upon the injection, of which a small percentage of patients complain, is due to the insulin solution being slightly acid and distinctly hypotonic. If the sting were to be experienced, say, a few times or perhaps limited to 50 times, few patients would complain, but since many must be stung 700 times a year, it is surely worth while attempting to save them the discomfort. The manufacturers informed me that there are difficulties in dissolving insulin in isotonic solution, and that it is essential for the solution to be acid. The reasons were communicated to me, but are not of general interest. The method of overcoming the discomfort is by rendering the injection practically neutral—i.e., to a hydrogen-ion concentration of pH 7·6 and isotonic with blood. For instance, a solution containing 1·8 per cent. sodium chloride and N/1000 sodium hydrate when mixed with equal parts of one commercial brand of insulin will render the injection painless. It is true that the mixture will become cloudy owing to the precipitation of the insulin, but experience has shown that this suspension of insulin is just as efficient when injected as the solution of insulin. Naturally, the injection must be made very shortly after the two solutions have been mixed. I have found that small children who dreaded the sting now receive the neutral isotonic mixture with a smile.

(3) The inflammatory reaction developing hours after the injection of insulin has become rarer since insulin has become more and more pure. But even now a very small percentage of people develop it after the injection of one kind of insulin, and may not after the injection of another. Usually some brand of insulin may be found which satisfies the patient.

I am, Sir, yours faithfully,
May 13th, 1924. O. Leyton.

Medical News.

University of Cambridge.—At a congregation held on May 17th the following medical degrees were conferred:—

M.D.—C. M. Billington and *A. S. Burgess, Caius: D. V. Pickering, Emmanuel; and B. E. Jerwood, Sidney.
B.Ch.—W. H. Craib, Caius; J. C. Ainsworth-Davis, Christ's.
* Admitted by proxy.

University of Oxford: *Radcliffe Prize.*—The next award will be in March, 1925. The prize, which is of the value of £50, is awarded by the Master and Fellows of University College, Oxford, every second year for research in any branch of medical science, comprised under the following heads: human anatomy, physiology, pharmacology, pathology, medicine, surgery, obstetrics, gynæcology, forensic medicine, hygiene. The prize is open to all graduates of the University who have proceeded, or are proceeding, to a medical degree in the University. Candidates must send in their memoirs to the Assistant Registrar, at the University Registry, on or before Dec. 1st, 1924.

University of Paris.—The Faculty of Medicine of the University announces a post-graduate course to be held at the Clinique médicale de l'Hôtel Dieu from June 30th to July 11th under the direction of Prof. M. A. Gilbert and Dr. M. Maurice Villaret. The subject of the course will be Recent Medical and Chirurgical Advances in Diseases of the Liver, of the Biliary Passages, of the Pancreas, and in Connexion with Diabetes. The course will consist of 32 meetings and will be provided with abundant illustrative clinical material. It is open to all qualified medical men and a laboratory fee of 150 francs is charged. The full programme and further particulars may be obtained from the Secretary, Faculté de Médecine, Université de Paris.

Royal College of Surgeons of Edinburgh.—At a meeting of the College held on May 16th, Sir Harold J. Stiles, President, in the chair, the 19 successful candidates out of 36 entered, who passed the requisite examinations between Jan. 14th and 18th, 1924, were admitted Fellows:—

John S. Bow, William G. H. Cuscaden, Thomas Gardner, Arthur J. C. Hamilton, David Huey, Shankar R. Joglekar, Ratenshah N. Kapadia, Havelock T. Lippiatt, Malcolm R. MacCharles, James S. McLaren, Otto W. Niemeier, John S. O'Neill, Montague M. Ostrowick, Richard R. M. Porter, Kenneth M. Purves, Douglas H. Saunders, Frederick N. Spittel, Harry W. Whytock, and George A. W. Wickramasuriya.

At the same meeting the Bathgate Memorial Prize, consisting of bronze medal and set of books, was, after a competitive examination in Materia Medica, awarded to Mr. Cecil A. S. Hamilton.

The following candidates having passed the requisite examinations received the Higher Dental Diploma:—Geoffrey M. Yardley, Robert M. Meldrum, and Wilfred J. J. Craig.

Aberdeen University Club.—The bi-annual dinner of the Club will be held at Gatti's Restaurant, Strand, London, W.C. 2, on Saturday, May 31st, at 7.30 P.M. Prof. Harrower will preside. The hon. secretary, Dr. W. A. Milligan, 11, Upper Brook-street, W. 1, will be pleased to hear from either past or present graduates (men or women) wishing to join the Club or attend the dinner.

FEDERATION OF MEDICAL AND ALLIED SERVICES.—The Prime Minister will attend the annual dinner of the Federation on June 20th, as will also the Minister of Health and Sir William Joynson-Hicks, M.P., the late Minister of Health. It is particularly requested that applications for tickets, price 12*s.* 6*d.*, be made to the Secretary as early as possible, at 12, Stratford-place, London, W. 1. The function will provide an excellent opportunity for medical men and their friends to meet prominent political and business men interested in preventive medicine.

CHADWICK PUBLIC LECTURES.—A lecture (illustrated by lantern slides) on Women in Dangerous Trades, by Miss Constance Smith, will be given in the Lecture Hall, Bedford College, Regent's-Park, N.W., on Tuesday, May 27th, at 8 P.M. Miss Tuke will be in the chair.—On Wednesday, June 4th, at 5.15 P.M., an open-air lecture will be given by Sir David Prain in the Chelsea Physic Garden, Swan-walk, Chelsea, on the Economic and Hygienic Relationships of Cinchona Bark and its Alkaloids. Sir William J. Collins, chairman of the Chadwick Trustees, will be in the chair.

ROYAL SANITARY INSTITUTE.—A sessional meeting of the Institute will be held on Friday, May 30th, in the Royal Spa Rooms, Harrogate, at 5.15 P.M., when discussions will take place on Public Health Services—Are They Worth the Money Expended ? to be opened by Dr. J. R. Kaye, medical officer to the West Riding County Council. Openers of the discussion from the point of view of Medical Officer, Dr. J. J. Buchan (Bradford) ; Sanitary Inspector, Mr. T. Foley Cass (Chief Sanitary Inspector, Hull) ; Health Visitor, Miss A. Brooke (Inspector of Midwives and Health Visitors, W.R.C.C.). The chair will be taken by Dr. John Robertson. Those proposing to attend the meeting should notify Dr. J. Mair, medical officer of health, 5, Haywra-crescent, Harrogate, immediately.

MILK-SUPPLY TO HOSPITALS.—An arrangement has now been completed under which the Hospital for Sick Children, Great Ormond-street, and the National Hospital for the Paralysed and Epileptic take between them the entire milk output of a dairy farm. The farm, which is situated at West Hill House, Culworth, Banbury, is open to the inspection of representatives of the hospitals, and the milk, after its arrival in London, is submitted to a series of tests for food values and absence of deleterious substances. The conditions under which the milk is produced are ideal. The cows are milked by Vaccar milking machines, and every vessel with which the milk comes in contact has been subjected to sterilisation by steam. Finally the milk is placed in hermetically sealed churns, which are not opened until they reach the hospitals. For the children in the Great Ormond-street institution the milk is pasteurised in bottles before being delivered to the wards.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—The programme for the month of June comprises a special course in Gynæcology at the Chelsea Hospital for Women covering the whole month, commencing on June 2nd ; and a series of eight clinical demonstrations from June 3rd to 27th on the more important diseases of tropical countries by Dr. G. C. Low and Dr. P. H. Manson-Bahr at the London School of Tropical Medicine. In addition to the foregoing there will be an intensive course at the Royal Northern Hospital in conjunction with the Royal Chest Hospital (City-road) from June 16th to 28th. Beginning on June 16th, and continuing until July 12th, will be held a four weeks' course in Urology at St. Peter's Hospital for Stone. Clinical work will be available daily and lectures given dealing with the various aspects of urinary disease. Also commencing on June 16th to July 4th, a two weeks' course on Diseases of Children at the Children's Clinic (Western General Dispensary). For full particulars of the above courses application should be made to the Secretary, Fellowship of Medicine, 1, Wimpole-street, London, W.1.

BRUSSELS MEDICAL CONGRESS.—The Fourth Congress, known as the "Journées médicales de Bruxelles," will be held in the Palais d'Egmont from June 29th to July 2nd under the patronage of the King and Queen of the Belgians. During the four days of the Congress, which is open to medical men and women, clinical demonstrations and operations will be shown in the hospitals during the forenoon, and in the afternoons lectures and cinematographic illustrations will be given. A very interesting programme has been arranged, and among those attending the Conference will be Dr. Alexis Carrel, of the Rockefeller Institute of New York, Prof. Bordet, and Dr. Levaditi. On the fourth day the Congress will be held at Liége. During the Congress an exhibition of pharmaceutical products, surgical instruments, and hospital furniture will be held in the Palais d'Egmont. The fee for the Congress is 40 francs, and further information, together with full programme, may be obtained from Dr. René Beckers, general secretary, 36, rue Archimède, Brussels.

ROYAL MICROSCOPICAL SOCIETY.—The section of the Society which has been formed to deal with the Industrial Applications of the Microscope, and to assist in the development of Industrial Research in British Industries, will hold its next meeting at 20, Hanover-square, W., on Wednesday, May 28th, at 6.30 P.M., Mr. A. Chaston Chapman, F.R.S., presiding. Mr. J. E. Barnard, F.R.S., will give a résumé of the whole subject ; and communications will be made by Mr. E. Sheldon Leicester on the Use of the Microscope in the Examination of Paper, and Mr. Kenneth MacLennan on the Microscopy of Soaps. Messrs. R. and J. Beck, Ltd., and Messrs. Ogilvy and Co. will demonstrate some optical exhibits. Further particulars may be obtained from the hon. secretaries to the Section, at 20, Hanover-square, London, W. 1.

DUBLIN : THE HOSPITALS AND THE GAS STRIKE.—Recently the workers of the only gas company in Dublin went on strike, with the result that users not only in the city, but in all the suburbs for miles round have been left without gas, and much inconvenience and even hardship have resulted. In the hospitals and scientific laboratories there is also much inconvenience, from which the sick have to suffer. Sterilisation of dressings and instruments has become a matter of great difficulty, and X ray departments are in many cases held up. Bacteriological incubators have grown cold, and it is quite possible that some strains of organisms will perish. The inconvenience has been increased by the neglect of the gas company to warn its customers of the likelihood of a cessation of work until a few hours before the supply ceased, although there was nothing in the nature of a "lightning strike."

CO. GALWAY HEALTH SCHEME.—In pursuance of the resolutions passed at a recent meeting of the medical profession of Co. Galway, already reported in THE LANCET (May 3rd, 1924, p. 918), a deputation waited upon the Minister for Local Government last week for the purpose of laying before him their views in connexion with (1) the scheme of the Galway Co. Board of Health for the rearrangement of the dispensary districts and the reduction of the number of dispensary medical officers ; (2) the lack of hospital accommodation for the sick poor and the necessity for providing cottage hospitals in the county. The deputation urged on the Minister the necessity, both in the interests of public health and the sick poor, of providing a number of cottage hospitals in different parts of the county for the treatment of acute cases of illness where removal to the Central Hospital at Galway would expose the patients to grave risks, and where the home surroundings did not permit of efficient medical treatment. In reply, the Minister assured the deputation that there would be no reduction in the number of dispensary districts in the county, but that, as vacancies arose, the existing district arrangements would be open to review. He undertook to consider fully the question of providing cottage hospitals.

DONATIONS AND BEQUESTS.—Mrs. Lucy Forrest, of Marlow, Bucks, left £500 each to the Marlow Cottage Hospital and the Marlow Provident Nursing Association.—Mr. William Smith, of Honeybourne, Gloucestershire, who left estate valued at £26,261, gave it on trust as to one-fourth each to the following institutions : the Evesham Hospital, the Worcester Infirmary, the Stratford-on-Avon Hospital, and the Birmingham General Hospital.—Under the will of the late Miss Florence Annie Holmes, of Hove, Sussex, the Hove Hospital will benefit by a sum of £500.

THE LATE MR. WALTER THOMPSON.—The death of Walter Thompson, F.R.C.S., took place on May 12th at Headingley Leeds, at the age of 58. Mr. Thompson was a Yorkshire man, and was the son of a farmer in Wharfdale. He pursued his medical studies at Leeds and Berlin, qualified M.R.C.P. in 1887, and in 1891 became a Fellow of the Royal College of Surgeons of England. Mr. Thompson has for many years been an honorary surgeon and later consulting surgeon on the staff of the Leeds General Infirmary, and held honorary surgical appointments at other hospitals, including the Coronation Hospital, Ilkley, and the Malton Cottage Hospital, the Leeds Public Dispensary, and the Women's and Children's Hospital. During the war he rendered valuable service at Salonica, although he was not in the best of health when he volunteered for active service. He held the rank of Lieut.-Colonel in the R.A.M.C.T. On his return from Salonica Mr. Thompson was appointed head of the Beckett-street Military Hospital, in which he did much successful work until the end of the war. For some years he was Lecturer on Practical Surgery in the University of Leeds. Last November he was operated on for an internal malady by his close personal friend, Sir Berkeley Moynihan. His death was felt as a distinct loss to the medical profession both in Leeds and the surrounding district, and the esteem in which Mr. Thompson was held was attested by the large number of medical men from Leeds and district who attended his funeral.

NORTH-WESTERN TUBERCULOSIS SOCIETY. — An address, illustrated by lantern slides, will be given by Mr. H. Morriston Davies at the next meeting of this society, to be held at the Tuberculosis Offices, Joddrell-street, Deansgate, Manchester, on Thursday, May 29th, at 3.15 P.M.

CONFERENCE ON SCIENCE AND LABOUR.—This Conference, which has been arranged by the British Science Guild in coöperation with the National Joint Council of the Trades Union Congress and the Labour Party, will be held at the British Empire Exhibition on May 30th and 31st, and will be opened by the Prime Minister. There are to be five sessions, the subjects of discussion being: (1) the Place of Science in Government; (2) Scientific Research in Relation to Industry; (3) Coöperation of Science and Labour in Production; (4) Science and the Human Factor; (5) Science in Educational Organisation. The fourth meeting will deal with Health and Psychology. Miss Margaret Bondfield, M.P., will preside, and the speakers include Sir Arthur Newsholme, Dr. C. S. Myers, Dr. Cyril Burt, and Miss May Smith. Copies of the programme and tickets of admission may be obtained by application to the Conference Secretary, 15, Gower-street, London, W.C.1.

MEDICAL EXAMINATION OF YOUNG PERSONS FOR FACTORY EMPLOYMENT.—The report of the Departmental Committee appointed by the Home Office to investigate this subject has now been issued (H.M. Stationery Office. Cmd. 2135. 6*d.*). The personnel of the Committee are Mr. Rhys J. Davies (chairman), Mr. Gerald Bellhouse, Dr. R. Wallace Henry, Mr. J. Moore Murray, Mr. Sydney W. Pascall, Mrs. Clara D. Rackham, Mr. W. J. Tout, and Mr. Arthur H. Wood, with Miss Rose E. Squire as secretary. The Committee have come to the conclusion that the present system is defective in the following respects: (*a*) The form of certificate is unsatisfactory in that it is negative, not positive; (*b*) the medical examination is, with certain notable exceptions, superficial and sometimes purely perfunctory; (*c*) re-examination during employment in a factory is unprovided for; (*d*) coördination with the school medical service and other public health services of the locality is lacking; (*e*) suitable accommodation in the factory for the medical examination is often absent and its provision is not compulsory. The more important of the recommendations for arrangements to be adopted in the future are that the age for examination should be raised from 16 to 18 years; that the form of the certificate should be positive instead of negative—i.e., it should be to the effect that the young person is physically fit for employment in the factory; and that the standard of examination, the form of certificate, and the nature of the conditions which may be attached to qualified certificates should be prescribed by the Home Office, which should supervise the work of the surgeon. A retaining fee should be paid to the surgeon out of public funds for the examination of factory processes, the making of an annual report, and re-examinations of employees when required. The fee for examination on entering employment in a factory should continue to be paid by the occupier. It is, moreover, recommended that the local authorities should at once be invited to submit schemes for taking over examination and certification of young persons, and that the aim in view should be that if the voluntary trial made by local authorities proves successful, the transfer of the whole of this work to the local authorities should be ultimately effected by order of the departments concerned.

HOUSE OF LORDS.

THURSDAY, MAY 15TH.

CRIMINAL RESPONSIBILITY (TRIALS) BILL.

Lord DARLING, in moving the second reading of the Criminal Responsibility (Trials) Bill, said its object was to alter the law in one important respect regarding trials where the insanity of the person accused was alleged. The Committee which was appointed by the late Lord Chancellor, Lord Birkenhead, to inquire into this question made a report some months ago, and he thought that action would have been taken by someone far more capable than he could pretend to be. But nothing had been done. He was perfectly well aware that there would be considerable opposition to the Bill he now brought forward, which might develop into a pitched battle. But it had often happened that some poor *franc-tireur* had begun what had in the end become a most important victory. The law had long been that insanity as recognised by the law of England entitled the accused person to escape capital punishment. Until 1883 the law was that in such a case, if the jury came to the conclusion that the accused was insane, the verdict was "Not guilty," because the accused was insane at the time of committing the crime; and therefore the accused was ordered to be detained during His Majesty's pleasure in a lunatic asylum. One of the improvements he desired to make involved the repealing of the statute of 1883, for the passing of which there were no good reasons. The 1883 Act altered the law in this respect: that if a person was proved to be insane the verdict was to be "Guilty of doing the act charged, but insane at the time." That was perfectly illogical and indefensible, and one of his proposals, which he hoped might induce their lordships to read the Bill a second time, if the rest had to be thrown over, was to bring back the law to what it was before this absurd statute was passed.

His reason for bringing in this measure was that there had long been a contest between the medical specialists and the law. These medical specialists had contended, and still contended, that directly they said that a person was insane in their sense he should be absolutely unpunishable, no matter what crime he may have committed. Some of them called themselves determinists; some of them contended that human beings were merely automatic creatures who acted with no control whatever over their motives or their actions. The law of England had never recognised that and he hoped never would. But it had recognised that a person might be insane in a legal sense and so entitled to a verdict of "Not guilty" where the act done, if done by a sane person, would involve a verdict of "Guilty" and a following punishment. It was so long since the law stood in that position that no doubt there must be some modification owing to modern research and recent knowledge. The noble and learned lord went on to refer to the murder in the year 1843 of Mr. Drummond, secretary to Sir Robert Peel, by a man named McNaghten. McNaghten was acquitted because insane, and he imagined that there was great public dissatisfaction with the result. As a result the judges were summoned to the House of Lords to give their opinions, and those opinions had been embodied in the Common Law of England ever since. Those opinions were expressed in certain statements known as the Rules in McNaghten's Case. Whenever a judge summed up in a case of murder he laid down the law in the terms of the advice then given. The two rules which mattered were these: The jury were told to inquire whether when he did the act which resulted in the death of the man the defendant knew the nature and quality of the act that he was doing; and to answer this further question: Did he know that the doing of the act was wrong? If so he was guilty. If he did not know this then he was not guilty on the ground that he was insane. Doctors of all descriptions had quarrelled with this and had said that it took no notice of a further possibility—that it simply dealt with the intellectual qualities of a man, and these were not exhaustive in the case of insanity. It was desired to add to the Rules in McNaghten's case another rule which he had ventured to propose in the present Bill. The McNaghten Rules were printed in the Bill, and it was desired to add to them that the accused was entitled to a verdict of not guilty on the ground that he was insane "if at the time the act was done or omission made which caused the death, he was suffering from such a state of mental disease as therefrom to be wholly incapable of resisting the impulse to do the act or to make the omission." That introduced what was known as the doctrine of irresistible impulse, which he recognised was a most controversial matter.

The noble lord, after quoting from pronouncements from high judicial and legal authorities on the subject, said he would like to ask Lord Sumner, who he understood was to move the rejection of the Bill, to state categorically whether he and those who thought with him recognised that there was actually such a thing as uncontrolled impulse due to disease of the mind. If they said "No" then they were in direct conflict with practically all the medical opinions of the day. If they said "Yes," then he asked further: Why have the man condemned; why not find that he was not guilty, because he could not control himself, and send him to a lunatic asylum? The Committee appointed by Lord Birkenhead on this matter were not psychologists or medico-psychologists. They were all practising lawyers with a good deal of experience in such matters. That Committee stated in their report: "It was established to our satisfaction that there are cases of mental disorder where the impulse to do a criminal act recurs with increasing force until it is, in fact, uncontrollable. . . . We appreciate the difficulty of distinguishing some of such cases from cases where there is no mental disease, such as criminal acts of violence or sexual offences where the impulse at the time is actually not merely uncontrolled, but uncontrollable. The suggested Rule"—(that was the Rule which he (Lord Darling) had put in this Bill)—"however, postulates mental disease; and we think that it should be made clear that the law does recognise irresponsibility on the ground of insanity where the act was committeed under an impulse which the prisoner was, by mental disease, in substance deprived of any power to resist." He simply asked their lordships to declare to be the law that which the Committee recommended should be made the law. The Rule as he would have it was already the law in Germany, Italy, South Africa, and Queensland. He would not trust juries to decide this or any other important question unless they received proper and adequate direction on points of law, but where they received such direction he believed juries were as sure as they could make sure of things in human affairs to come to a right verdict and to a verdict which satisfied the public conscience.

Lord SUMNER, in moving the rejection of the Bill, said it proposed to alter the law relating to the responsibility for crime committed by persons suffering from mental disease in a wholly novel and radical way. If their lordships gave the Bill a second reading they would give to this principle an approval which would be of the greatest gravity and which would make the Committee stage a wholly minor matter. Speaking for himself, he did not understand what was the supposed frame of mind in which a person did know the physical nature and quality of his act and did know that the act done was wrong and, notwithstanding, was suffering from such a state of mental disease that he was wholly incapable of resisting the impulse. He did not think it was right to add to the puzzles which juries had to solve by needlessly complicating the questions put to them in this sort of way. But since Lord Justice Atkin's Committee, adopting the view of a number of medical men who came before them, had said that it was established to their satisfaction that there were such cases he was prepared to accept their better opinion and agree that such cases there were.

As to why such a person should be condemned there were two or three answers. For 80 years such a person had been condemned if the jury had been of the opinion under the direction of the judge that he was not insane, and he did not notice in the report of the Committee or in the speech of Lord Darling that there had been any serious attempt made to show that actual injustice had ever occurred. Cases of mothers seized with an impulse to cut the throats or otherwise dispose of their offspring to whom they were normally devoted were not uncommon, but he never knew that there was any difficulty with regard to those cases. The wretched person no doubt was sentenced to death, but the exercise of the prerogative of mercy was as certain as that the sun would rise next day. Could it be that they wanted more than the exercise of the discretion of the judge for the purpose of dealing with cases which were not very numerous and in which they would not succeed in satisfying the medical profession? Their lordships who read the very interesting report of the Committee will find that there were two schools represented before it. One was that of an institution bearing the somewhat appalling title of the Criminal Responsibility Committee appointed by the Medico-Psychological Association of Great Britain, and they stood up for what he understood to be the view of alienists of the extreme school, the view that the law could not define insanity, that judges could not direct juries as to what was insanity, and that the only way in which these cases should be tried was to let the medical expert tell the jury what he thought about it, and then let the jury say for itself, out of its own head, whether a man was to be convicted or acquitted. There were even persons who went further than that, and said the inquiry ought not to take place in the presence of a jury, or by a jury, but in camera, by medical men specially qualified to pronounce whether minds were diseased or not.

The defence of insanity was constantly a speculative defence, raised on the chance of getting round the jury somehow. It was also in a large number of cases a rich man's defence. He greatly dreaded not that there would be an increase in the number of murders, but a considerable increase in the number of crimes of violence on women and children if a defence like this should be legal and should once have a success. Before they paid very much attention to the medical side of this question they ought to weigh against it the opinion and experience of the judges of England. He did not think there had been any serious dispute or criticism from the judges, and very little from the legal profession of the adequacy and substantial justice of the Rules in McNaghten's case. He was satisfied that criminals were deterred both by the certainty of punishment and the fact that it was speedy and that it would be a mistake to remove from these irresponsible beings that outside pressure which was exerted at present by the knowledge that if they failed to control what they ought to control they might find themselves punished by the law. Above all, they ought to consider not so much the fortunes or interests of a particular criminal, but the cause of the public at large.

Lord HEWART, Lord Chief Justice of England, in supporting the motion for rejection of the Bill, said he had not had an opportunity of consulting all his colleagues, the judges of the King's Bench Division, who were also the judges of the Court of Criminal Appeal, upon this matter. But he had consulted 12 out of 15. Of these 10 were like himself emphatically opposed to the measure, one was emphatically in favour of it, and one was doubtful. In cases where there was evidence of real mental disease antecedent to the commission of the alleged crime, and there was no evidence of a motive which might influence a sane person, juries had no difficulty in finding either that the accused did not appreciate the nature of his act or that he did not know it was wrong. But in cases where there was no such evidence of mental disease antecedent to the alleged crime mental experts might be found to say that the alleged crime itself afforded evidence that it was committed under irresistible impulse and that it might on that ground be inferred that there was mental disease. If that was so, the result might be to transfer to the medical profession the responsibility of the law in regard to a great number of ordinary criminals. Lord Darling had said that as medical science grew and as knowledge grew it was right that the criminal law should keep pace with it. Did his noble friend really mean that from time to time, as medical theory expanded, the rules of the criminal law were to be modified? Was it not far safer to say: Let medical science come with new meaning, with a changed meaning. The law would, however, still ask: Is this person to be excused because he did not know what he was doing, or if he did, because he did not know that what he was doing was wrong?

The LORD CHANCELLOR (Viscount HALDANE) said that almost invariably if a proposition was brought before the jury that the prisoner was through mental disease incapable of resisting the impulse to commit the crime somebody would be found to come forward and give expert evidence that a state of mental disease existed. He was not saying a word against the advance of medical science, which had been so notable during the last few years, or against the advantages of bringing psychology to bear where it could be useful. These scientists were excellent servants, but they were not always reliable masters. We had not recognised in this country the passion crime which was recognised on the Continent, and he hoped we should not recognise it. For his part, having given all the thought he could to the subject and read the admirable report of the Committee through and through, he could not bring himself to see that it would be a good addition to the law to introduce this new proposition. He was therefore unable to support the Bill.

Lord DUNEDIN, formerly Lord Justice-General of Scotland, and Viscount CAVE, formerly Lord Chancellor, also opposed the Bill.

Lord DARLING intimated that as his proposal had not been supported in debate he did not feel justified in asking that the Bill should be read a second time.

Lord Sumner's motion for rejection was formally agreed to.

Panel Doctors' Remuneration.

The National Insurance (Cost of Medical Benefit) Bill passed through Committee and was reported without amendment.

TUESDAY, MAY 20TH.

Tramways and Waterloo-road Hospital.

On the motion for the second reading of the London County Council (Tramways and Improvements) Bill,

Lord DENMAN moved that it be an instruction to the Committee to strike out from the Bill all powers relating to the construction of a short line of tramway, the proposed route of which passes the Waterloo-road Hospital. He said that this hospital was doing good work and the noise created by passing trams might have an injurious effect upon the patients, as had been the case in regard to St. Thomas's.

Lord MONK BRETTON said that he had a great deal of sympathy with the suggestion that hospital patients should be kept as quiet as possible, but there were ten large hospitals in London, including St. Thomas's, which had trams running past them. It was an unreasonable thing for Lord Denman to propose that this part of the Bill should be struck out after the measure had been passed by the House of Commons and when it was promoted with the concurrence of every party on the London County Council.

The Earl of DONOUGHMORE, Chairman of Committees, said he would not feel justified in asking their lordships to do otherwise than follow the usual course of sending this Bill to a Committee. If the worst came to the worst no doubt this hospital could be just as well carried on elsewhere. He did not wish to pronounce upon the merits of the case, but he hoped that Lord Denman would be satisfied with having called special attention to this matter and would allow the usual course to be followed.

Lord BUCKMASTER and Lord MONTAGU OF BEAULIEU supported the proposed instruction.

On a division the instruction to the Committee was carried by 57 votes to 35.

The National Health Insurance (Cost of Medical Benefit) Bill was read a third time and passed.

HOUSE OF COMMONS.

WEDNESDAY, MAY 14TH.

Vivisection (Prevention of Public Expenditure) Bill.

Lieut.-Commander KENWORTHY, in asking leave to introduce a Bill to prevent the payment out of public funds of moneys for experiment on living animals, said that the measure in no way interfered with experiments being carried out by private experimenters under licence as at present, but a large sum of money was being spent by the Ministry of Health in subsidising these experiments. Last year, as far as he could gather, they spent £130,000, which was much too large a sum, and objectionable for many reasons. It would be much more valuable if this money could be spent on providing milk for expectant mothers, and in helping crêches in poor districts and for other useful purposes. He did not intend to interfere with bacteriological experiments or with ordinary medical research experiments, but only as regards these particular experiments.

Dr. SPERO submitted that more money rather than less should be spent on animal experiments. In such experiments animals were under an anæsthetic and felt no pain whatever. Insulin had to be tested on rabbits before it could be given to human beings. Without experiments on animals, therefore, there would be a number of diabetic patients who would not be alive. Adrenalin, which was used for hæmorrhage, pituitary during childbirth, and a number of other preparations were all of animal extraction. No doubt his hon. friend in the years to come would give up his anti-vivisectionist views and resort to the rejuvenating properties of monkey glands. Again, some drugs had to be standardised, and that must first be carried out on animals. The best-known drug in that category was salvarsan, used in the treatment of syphilis. If medical men were denied standardisation they would be unable to treat with safety that terrible disease. The national milk-supply was kept free from tuberculous bacilli by inoculating guinea-pigs with suspected milk. He would remind the House of the self-sacrificing work carried on by research workers. If they were denied animals they would be forced to experiment on themselves.

Leave was granted to bring in the Bill, which, beside Lieut.-Commander Kenworthy, is backed by Mr. Foot, Mr. Scrymgeour, Mr. Trevelyan Thomson, Mr. Ayles, Mr. Mills, Rear-Admiral Sueter, Mr. Wignall, Sir P. Richardson, and Mr. Hogge.

The Bill was read a first time.

Cost of Insurance Administration.

Mr. FOOT asked the Minister of Health if he was able to state what was the cost of administration for national health insurance cases in England, Scotland, and Wales respectively. —Mr. WHEATLEY replied : The total cost of administration of national health insurance in the year 1922 (including expenditure by all Government departments in connexion with the service) was as follows : England, £4,012,000 ; Scotland, £547,000 ; Wales, £288,500. There are no statistics available as to the cost of administration per case, if, as is assumed, the hon. Member means by a case an individual insured person who is actually in receipt of one or other of the benefits provided under the Acts. The total cost of administration given above represented in the case of both England and Scotland approximately 6*s*. 4*d*. per insured person per annum, and in the case of Wales approximately 7*s*., and was in each case about 13 per cent. of the total receipts from all sources. There has been a reduction as from Jan. 1st, 1924, in the maximum amount allowed to be appropriated for the administration expenses of approved societies.

Water-supplies in Rural Areas.

Mr. ERNEST BROWN asked the Minister of Health whether any regular inspection of water-supplies in rural areas was carried out by his department.—Mr. WHEATLEY replied : Regular inspection is not carried out by my department, because the primary duty of looking after water-supplies rests with the local authorities, but a general survey is at present being made.

Infectious Disease Grants.

Mr. HARDIE asked the Minister of Health what was the amount of the yearly grants given by the Government for the treatment of infectious diseases ; and the yearly amount rated for by local authorities for the same purpose.—Mr. WHEATLEY replied : The grants paid during the year ended March 31st last for the treatment of infectious diseases in England and Wales amounted to approximately £1,607,000. These grants were mainly in aid of the cost of the treatment of tuberculosis and venereal diseases, no grant being available generally for the treatment of the ordinary infectious diseases. The total amount paid out of the rates for the treatment of infectious diseases generally was approximately £5,088,000 in the financial year 1921–22, the last year for which complete returns are at present available.

The Health of the Navy.

Mr. CECIL WILSON asked the Parliamentary Secretary to the Admiralty for what year the last report on the health of the Navy had been published ; and for what year the next report would be published, and when.—Mr. AMMON replied : The report for 1921 has just been published. It is expected that the next report (for the year 1922) will be published by the end of the present year.

Maternity and Child Welfare Grants.

Lieut.-Commander KENWORTHY asked the Minister of Health why there was a decrease in this year's estimates on the grants for maternity and child welfare (Class VII., Vote 1, Subhead G.1) of £70,000 in the case of England, and of £2000 in the case of Wales, as compared with last year's estimates ; and whether every encouragement was being given to local authorities and voluntary agencies to help expectant and nursing mothers, and young children, under the Maternity and Child Welfare Act, 1918, and the Education Act of 1918.—Mr. WHEATLEY replied : As regards the first part of the question, the explanation is that the actual expenditure last year of local authorities and voluntary agencies for maternity and child welfare proved to be considerably below the provision made in the estimate for that year. The provisions made for grants in the estimate for this year is substantially in excess of the actual amount of grants paid last year, and includes the necessary provision for development of this service. The answer to the second part of the question is "Yes" so far as activities under the Maternity and Child Welfare Act, 1918, are concerned. Any question affecting the Education Act of 1918 should be addressed to my right hon. friend, the President of the Board of Education.

THURSDAY, MAY 15TH.

Final Pension Awards.

Sir CHARLES CAYZER asked the Minister of Pensions whether, in the case of men called up at the outbreak of war and who, having completed four years' continuous war service, were granted pensions on leaving the Army, especially men who were passed A 1 on mobilisation and left the Army B 3, and who had had their pensions upheld by three successive medical boards, he would grant these men life pensions, it being quite clear that in the case of men passed A 1 on mobilisation and B 3 on discharge the causes of their disabilities were entirely due to war service ; and whether, in the case of men who had successfully appealed against a final allowance, he would empower the Appeals Tribunal Board to assess the damages immediately instead of putting the men forward for a further medical board, seeing that the policy suggested would save the country annually a very large sum of money in administrative expenses.—Mr. F. O. ROBERTS replied : The case of every officer or man who has been on the pension list for four years or more has to be considered for a final award under the provisions of Section 4 of the War Pensions Act of 1921. Wherever the case is found to be suitable for a final award, such an award is made. I am glad to say that in about 250,000 cases final awards of life pensions have already been granted. With regard to the last part of the question, I may point out that wherever the appeal tribunal are able to assess compensation finally they do so, and their finding is acted upon by my department. It is only in cases where they are uncertain as to the prognosis of the case that they set aside the award made by the Ministry. The suggestion made by the hon. Member would not be practicable without legislation, and would very frequently not be in accordance with the best interests of the man concerned.

Treatment of War Neuroses.

Sir **VICTOR WARRENDER** asked the Minister of Pensions whether it was proposed to extend the present Ministry of Pensions hospital at Grantham into a hospital for neurasthenics.—Mr. **F. O. ROBERTS** replied: Patients suffering from neurasthenia have for some time past been admitted to this hospital for treatment. It is proposed, when accommodation is no longer required there for medical and surgical cases, to use the institution solely for neurological cases.

Regulation of the Use of Codeine.

Major **CHURCH** asked the Home Secretary for what reason codeine was omitted from the list of narcotics to which the Dangerous Drugs Act applied; and whether His Majesty's Government would advocate the inclusion of this drug in any forthcoming international convention for the restriction of the traffic in narcotics.—Mr. **HENDERSON** replied: The Dangerous Drugs Act was passed in order to give effect to the International Opium Convention of 1912, and codeine is not one of the drugs included in that Convention. I am advised that codeine is not generally regarded by medical opinion as a dangerous drug of addiction.

Bacillus of Foot-and-Mouth Disease.

Mr. **GRAHAM WHITE** asked the Minister of Agriculture if he had any information regarding the reported discovery of the bacillus of foot-and-mouth disease announced by Prof. Paul Frosch.—Mr. **BUXTON** replied: A communication was made recently by Prof. Frosch to a scientific society in Berlin, but the Professor did not fully disclose his method of procedure, and it is therefore impossible for others to confirm his experiments. It is understood, however, that full details will not be long delayed.

Tuberculosis in the Navy.

Sir **BERTRAM FALLE** asked the Parliamentary Secretary to the Admiralty the number of men invalided during the last 12 months from His Majesty's Navy through tuberculosis; how many of these were considered attributable to service; and how the decision as to whether tuberculosis was attributable to or aggravated by service was arrived at.—Mr. **AMMON** replied: The number of men invalided during the year 1923 for tuberculosis was 143. The number of attributable cases was three, apart from cases (if any) claimed to be due to war service. The latter would be dealt with by the Ministry of Pensions. The following method of arriving at a decision as to attributability to or aggravation by service is adopted when considering cases arising during the post-war period:—

Pulmonary Tuberculosis.—Attributability is only given in such cases arising: (1) By direct contact with another case, such as might occur in a sick berth rating from nursing, or from sleeping adjacent to a case; (2) from extraordinary exposure, or exertion on duty, such as war. Aggravation is given: (1) Where the medical history of the case has shown a definite tendency to lung disease and a sufficient continuity of such disease; (2) where there is a record of service in small craft, where the ventilation and cubic space are limited; (3) where the disease arises under climatic conditions which amount to more than the ordinary exposure incidental to naval service.

As regards other cases of tuberculosis, such as those arising in joints and localised organs, attributability or aggravation is only given in cases where there is definite evidence of injury to the part sustained on duty and where it is considered that the injury has caused a lighting up of the disease.

MONDAY, MAY 19TH.

Death-rate in Gold Coast Colony.

Mr. **JOHN HARRIS** asked the Secretary of State for the Colonies what was the death-rate by sickness and accident, respectively, in the gold mines of the Gold Coast Colony for the last complete year.—Mr. **THOMAS** replied: The death-rate from accident for the last complete year for which statistics are available—viz., 1921—was 1·39 per 1000 labourers daily employed. It has not been the practice to furnish figures of the death-rate from sickness. My predecessor, some time ago, directed that such statistics should be furnished, but I have not yet been able to obtain complete and accurate figures. The information which I have obtained, however, leads me to doubt whether the conditions of labour at the mines are satisfactory, and I propose to discuss the whole matter with the Governor at an early date.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

THE ROYAL SOCIETY, Burlington House, W.
THURSDAY, May 29th.—4.30 P.M., Prof. D. M. S. Watson, F.R.S.: The Structure, Evolution, and Origin of the Amphibia. (Croonian Lecture.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, May 26th.

ODONTOLOGY: at 5.30 P.M.
At the Royal College of Surgeons, by kind permission of the College.
Annual General Meeting:
Election of Officers and Council for 1924–25.
The Odontological Section of the Museum will be open for inspection by Members, and the Curator, Sir Frank Colyer, will show the specimens which have been recently added.

Tuesday, May 27th.

MEDICINE: at 5.30 P.M.
Annual General Meeting:
Election of Officers and Council for 1924–25.

Wednesday, May 28th.

COMPARATIVE MEDICINE: at 5 P.M.
Annual General Meeting:
Election of Officers and Council for 1924–25.
Paper:
Dr. F. E. Crew: Achondroplasia in Man and Animals, with Special Reference to the "Bulldog" Calf.
A discussion will follow, to be opened by Mr. Leslie Pugh.

Thursday, May 29th.

UROLOGY: at 8.30 P.M.
Annual General Meeting:
Election of Officers and Council for 1924–25.
Pathological Evening:
Members are requested to give early notice to Mr. Girling Ball, 77, Wimpole-street W., of any specimens they wish to show.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.
FRIDAY, May 30th.—8.40 P.M., Mr. Kenneth Walker: Paper on Epididymitis, preceded by a Demonstration of Clinical Cases, and followed by a Discussion.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, May 26th, to Saturday, May 31st.—CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL. Special intensive course (last week).—LONDON LOCK HOSPITAL. Clinical work daily. Lectures at Dean-street as follows: Mon., 5 P.,M. Mr. Gibbs: Antenatal and Postnatal Treatment of Syphilis; Tues., 2.30 P.M., Mr. McDonagh: Microscopical Demonstration, Leucocytozoon Syphilidis; Thurs., 4.30 P.M., Mr. Lawrence Abel: Treatment of Chronic Gonorrhœa in the Male.—MAUDSLEY HOSPITAL. Mon., 3.30 and 5.30 P.M., Dr. Bernard Hart: The Psychoneuroses; Tues., 4.30 P.M., Sir Frederick Mott: Brain Syphilis, its Symptomatology and Treatment; Wed., 2.30 P.M., Dr. Mapother: Demonstration in Clinical Psychiatry.—PRINCE OF WALES'S GENERAL HOSPITAL. Special intensive course in Medicine and Surgery (last week).

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, May 26th.—12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Bishop Harman: Eye Dept. 2 P.M., Mr. Simson: Diseases of Women.
TUESDAY.—10 A.M., Dr. Drummond Robinson: Gynæcological Operations. 11 A.M., Mr. Endean: Venereal Diseases. 2 P.M., Dr. Burrell: Medical Out-patients.
WEDNESDAY.—12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Pernet: Skin Dept. 4.15 P.M., Dr. Owen (Lecture): Infantile Disorders in the First Ten Days of Life.
THURSDAY.—11 A.M., Dr. Archer: Chemical Pathology. 12 noon, Dr. Scott Pinchin: Diseases of the Heart. 4.15 P.M., Mr. Donald Armour (Lecture): Head Injuries.
FRIDAY.—12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Dept.
SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children, 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M. In-patients, Out-patients, Operations, Special Departments.

ST. JOHN'S HOSPITAL, Leicester-square, W.C.
TUESDAY, May 27th.—5 P.M., Dr. Sequeira: Lupus Erythematosus.
THURSDAY.—5 P.M., Dr. Graham Little: Dermatitis Herpetiformis.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

Post-graduate Course.

Monday, May 26th.—12 noon, Dr. Greenfield: Lecture, Paths of Infection of Central Nervous System. 2 P.M., Dr. Hinds Howell: Out-patient Clinic. 3.30 P M., Dr. Aldren Turner: Clinical Lecture.

Tuesday, May 27th.—12 noon, Dr. Walshe: Lecture on Anatomy and Physiology of Nervous System. 2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Grainger Stewart: Lecture, Disseminated Sclerosis.

Thursday, May 29th.—12 noon, Dr. Walshe: Lecture on Anatomy and Physiology of Nervous System. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Walshe: Lecture, Clinical Disorders of Muscle Tone.

Friday, May 30th.—2 P.M., Dr. Gordon Holmes: Out-patient Clinic. 3.30 P.M., Dr. James Collier: Clinical Lecture.

Applications should be addressed to the Secretary, Medical School, National Hospital for the Paralysed and Epileptic, Queen-square, London, W.C. 1.

J. G. Greenfield, Dean.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

(At 4.30 P.M.)

Monday, May 26th.—Mr. Aubrey Goodwin: Curettage, its Uses and Abuses.

Tuesday.—Dr. C. E. Sundell: Nephritis in Children.

Wednesday.—Dr. J. Browning Alexander: Treatment of Gastric and Duodenal Ulcer.

Thursday.—Dr. A. J. Whiting: Vagus Effects on the Heart as Met with in Practice.

Friday.—Mr. H. W. Carson: Peritonitis—Treatment of.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

Thursday, May 29th.—4 P.M., Dr. Thursfield: Acholuric Jaundice.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)

Monday, May 26th.—(At the Children's Hospital.) Dr. H. Armstrong: Clinical.

Tuesday.—(At the Southern Hospital.) Dr. Macalister: Chronic Dyspepsia.

Wednesday.—(At the Northern Hospital). Dr. L. Cunningham: Rheumatic Fever.

Thursday.—(At the Stanley Hospital.) Mr. Morrison: Surgical Cases.

Friday.—(At the Royal Infirmary.) Dr. Matthews: Exhibition of Blood Films.

BRISTOL UNIVERSITY POST-GRADUATE DEMONSTRATIONS.

Wednesday, May 28th (at the Hereford General Hospital.)—3.30 P.M., Dr. O. C. M. Davis: Defective Dieting as a Cause of Children's Disorders.

Appointments.

Alexander, T. H. W., M.B., B.Ch. Edin., has been appointed Medical Referee under the Workmen's Compensation Act for Elgin and Nairn.

Bowes, G. K., M.D. Oxf., D.P.H., Asst. Medical Officer, Birmingham.

Caird, A. J., M.B., Ch.B. Edin., Hon. Asst. Surgeon to the Cumberland Infirmary.

Falconer, K., M.B., Ch.B. Glasg., Medical Officer of Health for Drolysden.

Lawson, Miriam A., L.R.C.P., M.R.C.S., Resident Medical Officer, St. Mary's Hospital for Women and Children.

King's College Hospital: East, C. F. T., B.M., B.Ch. Oxf., M.R.C.P. Lond., Radcliffe Travelling Fellow of the University of Oxford, Medical Tutor, and Junior Physician on the staff; Livingstone, J. L., M.B., B.S. Lond., Sambrooke Medical Registrar; Perkins, A. C. T., M.R.C.S., L.R.C.P. Lond., Second Casualty Officer; Townsend, H. S., M.R.C.S., L.R.C.P. Lond., House Anæsthetist; Lane, C. R., M.B., B.Ch., Resident Asst. Clinical Pathologist; Brockington, F., M.B., B.S., Smith, A. B., M.B., B.S., and Sheldon, W. P. H., M.R.C.S., L.R.C.P. Lond., House Physicians; Strange, F. O. T., M.R.C.S., L.R.C.P. Lond., Sommerville, A. C., M.R.C.S., L.R.C.P. Lond., and Connan, P., M.R.C.S., L.R.C.P. Lond., House Surgeons; Kohnstam, G. L. S., M.R.C.S., L.R.C.P. Births, Marriages, and Deaths.

BIRTHS.

Goode.—On May 13th, at Bootham, York, the wife of Henry Norman Goode, M.C., M.B., F.R.C.S.E., of a son.

Martin.—On May 14th, at Westbourne-gardens, W., the wife of E. Kenneth Martin, M.S., F.R.C.S., of Wimpole-street, of a daughter.

Rushworth.—On May 12th, at Orchard Corner, Walton-on-Thames, the wife of Arthur Norman Rushworth, M.R.C.S., L.R.C.P., of a daughter.

Shaw.—On May 14th, at Coronation-street, Barnstaple, Devon, the wife of Simeon Cyril Shaw, F.R.C.S., M.B., B.S., of a son.

MARRIAGES.

Fox—Gibson.—On April 23rd, at St. Peter Port Parish Church, Guernsey, William Barton Fox, B.A., M.B., B.Ch. (T.C.D.), to Doris Margaret Gibson, M.B., B.Ch. Edin., elder daughter of Dr. and Mrs. E. V. Gibson, Paradis," Grange-road, Guernsey.

DEATHS.

Foulds.—On May 9th, after an acute illness, Greta Maryanne Foulds, beloved wife of Dr. Francis Henry Foulds, of Severn House, Droitwich, aged 50 years.

McKinlay.—On May 17th, at Southsea, suddenly, Deputy Inspector-General Archibald McKinlay, R.N. (retired).

Scowcroft.—On May 17th, at St. Ann's Cottage, St. Ann's-road, Cheadle, Cheshire, Walter Scowcroft (late Medical Superintendent of Cheadle Royal, Cheshire), in his seventieth year.

Widegren.—On May 18th, at Grosvenor-place, Matthias W. E. Widegren, M.R.C.S., L.R.C.P., Knight of the Swedish Order of Vasa, aged 62.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

OUR CLOTHES AND HEALTH.

AT a meeting of the Maternal and Child Welfare Group of the Society of Medical Officers of Health held on May 15th, with Dr. H. Scurfield in the chair, Dr. Leonard Hill delivered a lecture, illustrated by lantern slides, on clothing and open-air treatment. The lecturer began by describing the properties of different cloth fibres and showed that in maintaining the warmth of the body the essential factor was not the nature of the fibre but its ability to retain air. This was brought about largely by the style of weaving. Air was a very bad conductor of heat, and the warmth of the body was retained by particles of air trapped in the meshes of the garment. He showed the results of his experiments with his instrument the katathermometer, which proved how the maximum amount of heat was to be retained when cellular clothing was covered on the outside with waterproofed or air-proofed material, thus preventing the warm layers of air from being carried away from the body. This principle was put into practical application in the clothing of airmen and Arctic explorers. With regard to wet clothes, Dr. Hill showed that wool retained the maximum of warmth in the body, as wool fibres when wet did not collapse as cotton and silk did. He made reference to some experiments which had been done at the instigation of the Board of Trade to test the most suitable provision to make for people who might be shipwrecked. The results of these experiments were that the essential factor in preserving life was warmth and that this could best be achieved by putting on some waterproof covering over the ordinary clothes whether these were wet or no. Dr. Hill then went on to show the effect of colour on heat retention. As is well known, white radiates and breaks up heat and light rays which are absorbed by black. He gave illustrations of several interesting experiments which went to prove this. The ideal clothing for tropical wear—as, for example, the wide white flapping garments of the Arabs—was that in which air was allowed to circulate freely throughout the body and which permitted the perspiration to evaporate. He showed that 1 g. of water in evaporating got rid of 600 calories. The white dweller in the tropics required to achieve pigmentation before he was able to withstand the sun's rays. Dr. Hill showed how the short ultra-violet rays of the spectrum had a very small penetrating power, so small indeed that though their bactericidal power was great the presence of one bacterium in front of another was sufficient to protect the lower one. Pigmentation of the skin is caused by the longer ultra-violet rays. Dr. Hill described the experiments which he was carrying out to determine the daily amount of ultra-violet rays in sunlight. His scale showed that half a degree was emanated during 24 hours when the day is cloudy, whereas 10 degrees were given off in the same period when the sun has been shining brightly. The lecturer urged the wider application of heliotherapy, and showed pictures of the work which is being done by Sir Henry Gauvain and Dr. Rollier. Ultra-violet light comes not only from direct sunlight but from the blue sky and is reflected from bright clouds. He hopes that cities will take up the task of estimating the daily amount of ultra-violet light in the atmosphere and will thus come to realise what a tremendous loss is sustained through the pollution of the atmosphere in large cities and will be shamed into coping with the smoke nuisance. Dr. Hill then gave experimental evidence to show the immense value of sunlight in the cure and prevention of rickets. Where, as in this country over large sections of the year sunlight was not very abundant, these curative rays could be obtained by means of the mercury-vapour quartz lamp. Such lamps were now installed in several London and provincial therapeutic centres. Dr. Hill advocated that children should always wear the minimum amount of clothing, and stated that even small babies were far less liable to take cold than was commonly supposed.

PUBLIC HEALTH IN CEYLON.

A REPORT on the affairs of the colony for the year 1922, prepared by Mr. C. H. Collins, second Assistant Colonial Secretary, has just been presented to Parliament. It includes a lengthy section devoted to vital statistics, public health, and kindred matters. From this we gather that, estimated on the basis of the census of March 18th, 1921, the population of the island, exclusive of the military and shipping on Dec. 31st, 1922, was 4,621,147, made up of 9100 Europeans, 30,250 Burghers and Eurasians, 3,087,308 Cingalese, 1,134,083 Tamils, 288,644 Moors, 13,721 Malays, and 26,453 others. The birth-rate of the year was 39·4 per mille and the death-rate 27·8 per mille of the estimated population. The mortality of children under 1 year of age amounted to 33,803, and corresponded to 26·7 per cent. of the total deaths during the year. The death-rate from some of the principal causes per million of the population is given in the subjoined table :—

Pyrexia	4422	Ankylostomiasis	410
Infantile convulsions	3028	Premature birth and congenital defects	363
Diarrhœa	2127	Puerperal septicæmia	338
Pneumonia	1640	Bronchitis	290
Phthisis	681	Enteric fever	119
Dysentery	551	Cancer	101
Influenza	525		
Malaria and malarial cachexia	449		

The deaths attributed to influenza during the year numbered 2395, the lowest total recorded since the pandemic broke out in 1918, when it was 19,092. The deaths from pneumonia, which since the outbreak of the influenza pandemic have been fairly high, amounted to 7479, an increase of 771 over the previous year and of 813 over 1920. But compared with the years 1918 and 1919 the mortality from pneumonia also is considerably less. It is likely that the increase over the previous two years of the deaths from pneumonia is due to a slight recrudescence of influenza in the second and third quarters of the year. The number of deaths from plague registered in the year was 143, of which only 23 were females. It is now nine years since the plague broke out in the island, and within this period there have been only two years—viz., 1915 and 1919—in which the mortality from the disease was less than in this year. As usual, by far the greater number of deaths occurred within the municipality of Colombo. There were 40 deaths registered from small-pox, and 4 from cholera. To accidents and other affections produced by external causes were attributed 1982 deaths ; 471 of the accidental deaths were returned as due to fall from trees, and of the number, strange as it may appear, 5 were females. Drowning was ascribed as the cause of death in 413 cases, and deaths from burns numbered 207 (27 being ascribed to the bottle lamp). 167 males and 82 females died from snake-bite. The death-rate per million persons from homicide was 48 and is comparatively high. Suicide accounted for the deaths of 167 males and 65 females. Parangi (frambœsia) is still prevalent in many parts but is less common than it was some years ago, the position having been very much improved by the restoration of many village tanks and the establishment of dispensaries. Special efforts have been made of late years to deal with the disease, which is treated with salvarsan in many district hospitals and three special itinerating medical officers have been appointed for work in selected areas. Special mention may be made of the very praiseworthy work of a private medical practitioner who has treated a very large number of parangi patients free in a number of villages in the North-West Province, using drugs supplied by Government with encouraging results. The campaign against ankylostomiasis, carried on conjointly by the Rockefeller Foundation and the Ceylon Government, has been continued during the year, and arrangements were made for training a number of inspectors for work in this department. All parts of Ceylon are well supplied with hospitals and dispensaries, most of which have been provided and are supported by the public funds. The island possesses a lunatic asylum which contained 1097 inmates on Dec. 31st, 1922, and two leper asylums, one at Hendala, which contained 455 patients at the end of the year, and the other at Mantivu with 116 lepers. A home for incurables of 80 beds is administered by a committee of Government officials and representatives of the public. There is a tuberculosis sanatorium at Kandana in the Western Province and 91 other Government hospitals, including a hospital for chronic cases of tuberculosis equipped with modern hospital furniture and surgical appliances. In addition to the hospitals there are 472 central and branch dispensaries, including a central institute in Colombo for tuberculosis cases, this last being fitted up with an X ray apparatus. The owners of estates have provided 64 estate hospitals, which received a rebate on export duty, and 542 estate dispensaries received drugs free from Government to the value of 50 cents per labourer per annum. The general scheme in contemplation for the rebuilding of the Ceylon Medical College remains deferred. The full course of training at the college is five years for the medical students and two years for the apothecary students. A diploma in medicine, surgery, and midwifery (which can be registered in the United Kingdom) is granted to the successful medical students. The apothecary students are employed by the Government after they qualify in the final examination. Colombo possesses a bacteriological institute, a Pasteur institute, a general hospital of 711 beds, an ophthalmic hospital, a lying-in home, a hospital for women and children, and a hospital for infectious diseases. There are special dispensaries at Kandy and Galle for the treatment of eye diseases. There is a marked variation in climate between the different parts of Ceylon. In the low country, with a mean temperature of the order of 80° F., a noticeable feature is the small range of both temperature and pressure. There is, however, wide divergence between the moist conditions in the south-west of the island, where the average annual rainfall varies from 100 to 200 inches, and the dry zone areas of the north, north-west, and south-east. Altitudes up to 8200 feet occur inland, and there the temperature is cooler and shows a bigger range. There is a corresponding change in vegetation, and the conditions are altogether more akin to those in the temperate zone. The death is recorded with regret of Dr. Alan Kidd, superintendent of the General Hospital, and it is mentioned that early in the year Dr. P. J. Kelly, registrar of the Medical College, was appointed Surgeon-General of British Guiana.

HEALTH CONDITIONS IN SWAZILAND AND THE SEYCHELLES.

Swaziland.

THE census taken in May, 1921, showed that the European population in the Protectorate was 2205, representing an increase of 103·6 per cent. since the 1911 census. The native Bantu population amounted to 110,295, an increase of 5·34 per cent. in the ten years. During 1922 the general health of the territory was fairly good. Small-pox was epidemic in a mild form. The number of deaths from the disease has been small. Vaccination work has been carried out and the bulk of the native population has been successfully vaccinated. There has been very little malaria during the year, and cases of enteric were rare. Syphilis continues to be a troublesome disease amongst the native population, but every effort is being made to deal with it. Only a few cases of influenza—of a mild type—occurred during the year. Out of 148 cases admitted to the hospital there were three deaths; 15,722 out-patients were treated. Swaziland is divided geographically into three longitudinal regions of roughly equal breadth, running from north to south, and known locally as the high, middle, and low or bush veld. The climate of the high veld has been likened to that of the south of France. The air is bracing and invigorating; light frosts are prevalent during the months of June and July. The mean temperature in winter is 57° F. The summer is pleasantly warm. The absolute maximum over a long number of years is 101°, while the mean temperature in summer is 67°. The rainfall is good, the average recorded at Mbabane over 19 years being 50·49 inches. The middle veld is well watered by streams rising in the ranges on the west. Lying as it does some 2000 feet below the mountains, the summer temperature of this area is warm and humid, but in winter is cool and refreshing. The mean temperature in summer is 72° and in winter 62°. Frost at times occurs in the valley streams, but is seldom found elsewhere. The rainfall recorded at Bremersdorp over 20 years averages 34·35 inches. East of and parallel to the middle veld lies the bush veld, about 20 miles in width and running north and south through the whole area of the territory. Many streams come down from the high veld and Drakensburg Range. These streams converge in the bush veld into five rivers. But for these this area is not well watered. The rainfall recorded at Natalie Ranch over eight years averages 26·64 inches. The high veld is free from malaria, which is, however, prevalent in the low veld and in a slight degree in the middle veld during some of the summer months. The malaria is not of a virulent type and is easily avoided by taking the precautions ordinarily considered necessary in any subtropical country.

Seychelles.

The Seychelles Islands are situated between the parallels of latitude 4° and 5° S.; the estimated total number of square miles comprised in the group and in the dependencies is 156½. The number of islands under the Seychelles Government is 90. Mahé is the largest and most populous, and is distant from Mauritius 934 miles, from Madagascar 600, and from Zanzibar 970 miles. It is mountainous, fertile, and extremely healthy. The total population of the colony on Dec. 31st, 1922, was estimated at 25,176, an increase of 653 since April, 1921. There were 108 marriages during the year, as compared with 119 in the previous 12 months. Births numbered 753, which corresponds to a rate of 30·47 per 1000. The deaths amounted to 344, or 13·92 per 1000. This is the lowest local record for many years and may be attributed to the fact that there were no epidemics of any infectious or contagious disease during the year. In spite of its proximity to the equator, Seychelles is reputed to be one of the most healthy of the British possessions within the tropics. Its climate is mild and equable. The maximum shade temperature rarely exceeds 86° F., while at night the temperature seldom drops below 74°. The rainfall averages about 90 inches, although in some years it has reached 165 inches.

SALFORD'S REMEDIAL PLAYGROUND.

THE annual report of the Greengate Dispensary, Salford, which has been in existence for 40 years, gives some interesting and suggestive information as to what can and has been done for improving the health of its little patients. The total attendances of out-patients was 6419, and 1029 were new cases who had not previously been attending. The opening of an open-air playground has invited new problems of personal care and of administration, and some remarkable results have been obtained. The number of living-in children of pre-school age will be increased to 20. The report of three years' work of the Greengate School is well worthy of attention. In the new open-air shed and playground the method of "individual work" in place of the previous method of formal class teaching has almost been completed. The principles adopted in the physical training of the puny and defective children from the start were the discontinuance of absolute rest in bed and use of splints as curative agents for the weak, ill-grown, and distorted limbs, and the substitution for the whole body, and especially for the development of the arms and the chest, approximate and spontaneous activity, fresh air, good nutrition, happy social surroundings, and full employment for the mind. By these means dormant vital processes and nerve activity were awakened and expressed themselves in a better circulation, ampler range of breathing, and an invigorated muscular response. By natural rather than artificial processes the distorted bones of the rickety children grew into their proper shape as part of a genuine process of healthy vigour of body and mind alike. The results were remarkable and the success is graphically attested by the series of photographs, which might well be labelled "before" and "after," in the report, and by the charts illustrating the attainment of normal growth in height and weight by rickety and deformed children under favourable circumstances. Dr. A. A. Mumford puts the matter tersely:—Away with splints and lying in bed, give the air and sun a chance, aided by good food and exercise and happy occupation for the mind. This is the basis of the wonderful results attained in the "remedial playground" situated in the midst of a dense slum area. The results achieved in this little school seem not far short of miraculous. The development begins almost at once, the children literally begin to live.

MOTHERCRAFT.

ANY normal woman who can produce a baby can nurse one. This is the faith insisted on in the section on lactation of an admirable little manual[1] by the matron of the Mothercraft Training Society, and is justified by the excellent results obtained at the Trebovir-road Clinic, which is its headquarters. Miss Liddiard discusses seriatim the difficulties that are met with from time to time in breast-feeding, and shows that they can nearly always be overcome. The teaching given with regard to the induction, management, and re-establishment of lactation is clear and uncompromising. The principles of artificial feeding, with hints on weaning and feeding after nine months, are also discussed. The little book is, however, more than a survey of feeding problems. It is an excellent summary of the whole science of mothercraft, and should be of considerable value to young and expectant mothers. It is really an epitome of the teaching given at the Trebovir-road clinic, for the benefit of those who are unable personally to attend the courses of lectures there. There are two or three useful chapters on the expectant mother and the necessary preparations for the advent of the baby; the care of premature babies and the home treatment of various small ailments are also dealt with, the book ending with a chapter of simple recipes. In an introduction to the volume Dr. J. S. Fairbairn points out that it is on the preventive side of the subject that emphasis is chiefly laid by the author, and rightly so, since "prevention is the vitalising force in present-day medicine."

OPENING OF A NEW L.C.C. MENTAL HOSPITAL.

THE Minister of Health will perform the opening ceremony at West Park Mental Hospital, Epsom, on Friday, June 20th, at 3 P.M. This is the eleventh mental hospital under the administration of the London County Council, and is planned to provide a detached building for each class of patient. The hospital as now built will provide accommodation for 1732 patients, and ultimately the completed building will contain 2096 patients.

Messrs. Chas. Hearson & Co., Ltd., are showing a complete selection of bacteriological, pathological, physiological, chemical, and research apparatus in the Spratt's Patent Pavilion near the British Government Building at the Wembley Exhibition.

An Address

ON

PUERPERAL SEPSIS:

ITS PREVENTION AND TREATMENT.

Read before the Ulster Medical Society at Belfast

BY BECKWITH WHITEHOUSE, M.B., M.S. LOND.,
F.R.C.S. ENG.,

HONORARY OBSTETRIC SURGEON, GENERAL HOSPITAL, BIRMINGHAM; ASSISTANT TO THE CHAIR OF MIDWIFERY AND DISEASES OF WOMEN, UNIVERSITY OF BIRMINGHAM; LATE HUNTERIAN PROFESSOR, ROYAL COLLEGE OF SURGEONS.

IN introducing the subject of puerperal sepsis for discussion this evening I make no excuse, inasmuch as it is a problem which to-day must command the serious attention of our profession. Unfortunately, throughout the civilised world the present death-rate from septic complications of childbirth is little better than it was 30 years ago. This has been emphasised in many recent writings. Eden, in 1922, drew attention to the increasing mortality from childbirth from 1911 to 1920, and pointed out that this increase was due to the factor of infection, deaths from other causes having actually decreased. Whitridge Williams, in the preface to the fifth edition of his classic on "Obstetrics," recently published, refers to the statistics of Howard and Eichel, which prove that in America childbirth was actually more dangerous in 1921 than in 1916. Furthermore, to quote Williams's words, "The death-rate is greater in urban than in rural communities, and that while reasonably satisfactory results are obtained in the largest cities, in which a considerable proportion of deliveries are cared for in hospitals conducted by trained specialists, they are superior in country districts to those obtained in the medium-sized and small towns."

This is a very interesting observation, and it is possible that it may have some bearing on the discrepancy that exists in the incidence of deaths from puerperal sepsis in England, Scotland, and Ireland respectively.

INCIDENCE OF PUERPERAL SEPSIS.

In Table I. and Chart 1 are shown the death-rate from sepsis as per 1000 births in the three countries for the ten years 1912 to 1922 inclusive. England is far and away the highest with an average death-rate of 3·3 per 1000. Scotland is lowest with a rate of 1·6 per 1000, and Ireland very near with a death-rate of 2·0 per 1000. Scotland and Ireland together have an average for the period of 1·8 compared with that of 3·3 for England. These figures, when compared with the corresponding number of births, bring to light the interesting observation that, as a general rule, the higher the birth-rate the greater is the individual maternal death-rate from sepsis. The average number of births per annum in the three countries over the same period is as follows:—

Scotland	115,329		

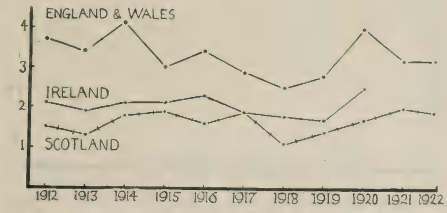
The remarkable rise in death-rate in the year 1920 which appears in all countries is reflected also in the total number of births, which shows a sudden increase after the fall during the years of the late war. The same fact is demonstrated in the English statistics over a longer period. The birth-rate in England is slowly declining, and with the fall there has been a slight diminution in the number of deaths from sepsis.

Years.	Births (average) per annum.	Maternal death-rate per 1000 (puerperal sepsis).
1883–1892	632,300	3·64
1892–1902	638,271	3·26
1912–1921	351,256	3·30

Ireland and Scotland consist largely of rural communities, contrasted with the thickly populated industrial areas spread over the greater part of England, and one cannot help but think that this may be one of the general causes which are responsible for the variation in the three countries.

The factors which govern the incidence of sepsis are chiefly centred in the large areas of population, and although ideal midwifery may be practised and taught in the large institutions, the great part of maternity practice in England to-day falls on the shoulders of the family practitioner, the midwife, and, I am afraid, the "handy-woman," who still, "sub rosa," plies her trade. In Birmingham, where my impressions have chiefly been gained, puerperal sepsis is all too common, just as it is in other large communities, although Birmingham compares very favourably with the country as a whole. In the year 1923 the notifications of puerperal fever in Birmingham numbered 185 (9·6 per 1000 births) and the deaths from this cause registered 34 (1·7 per 1000 births). Both notifications and deaths, however, are but a very rough index of the actual incidence of sepsis, inasmuch as the former do not include a very large quota of recoveries, and the latter only record the tragedies. In other words, a great number of cases undoubtedly occur which never see any register, but which help at a later date to swell the gynæcological out-patient departments and the consulting-room. Many a time have I been asked whether such and such a patient with pyrexia of 101° F. or over, and a pulse-rate of 120, should be notified as a case of "puerperal fever." My reply is that it is always advisable to consider serious morbidity in the parturient woman as due to sepsis, and that notification should always follow the demonstration of a streptococcus in a uterine swab. In other words, it is obligatory to make a bacteriological examination if the question of sepsis should arise, just as a swab is taken from the pharynx in the diagnosis of diphtheria.

CHART 1.



Deaths from puerperal sepsis per 1000 births from 1912 to 1922.

FACTORS CONCERNED.

I have referred to certain factors in the incidence of puerperal sepsis which preponderate in towns as compared with the country. What are these factors? One is undoubtedly the squalor and dirt in which many town-dwellers live, aided and abetted by overcrowding. Another is the bustle and rush which characterises the busy practice of the town practitioner. With a daily visiting list of 40 or 50 it is impossible to give the attention and detail to every midwifery case that is so essential to avoid sepsis every time. A third is the large number of cases which to-day are being attended by midwives, or by a doctor and midwife with the proviso that the doctor shall only be called in when necessary. This statement will probably be challenged, but I have been very much impressed during the last year or two by the number of cases of severe uterine sepsis to which I have been called by the practitioner after he in turn has been consulted by the midwife who delivered the patient.

The introduction of the Midwives Act in England in 1903 has, in my opinion, not been attended by the subsequent diminution of puerperal sepsis which might reasonably have been expected. Table II. and Chart 2 show the incidence of deaths from puerperal sepsis per 1000 births for the 20 years previous to the introduction of the Act. Compare this with the results of Chart 3 (last ten years). I think it will be agreed that there is little change. The same applies to the application of the Midwives Act for Scotland, which came into force Jan. 1st, 1916 (compare Table I.).

THE MIDWIFE.

The midwife, generally speaking, is an excellent woman who does her best for her patient, but the short training she receives prior to examination for the C.M.B. diploma cannot and does not ingrain in her the practical essentials of asepsis and antisepsis. It takes the medical student at least five years and members of the nursing profession three years in which to absorb the practical knowledge, and yet we grant many an uneducated woman a certificate to practise midwifery after a few months' theoretical training and a negligible amount of practical experience. The only proviso is that she shall call in medical aid under certain conditions, one of which is the occurrence of pyrexia—truly closing the door when the horse has escaped!

The trained nurse who takes the C.M.B. diploma is a very different proposition, especially if she has been surgically trained. Surgical cleanliness is a part of her unconscious self, and one cannot help wishing that the C.M.B. qualification had been reserved as a higher degree, so to speak, for the nursing profession. The trained "district nurse" who attends maternity cases is a very valuable asset to the medical profession and the public, and she should be encouraged to the exclusion of the uneducated and poorly trained individuals who to-day flourish in the big towns, and appear to make a very lucrative income from maternity practice in the working-class areas.

MATERNITY HOMES.

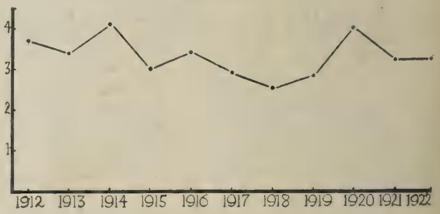
Whilst on the subject of the maternity nurse another point calls for consideration, and that is the maternity home. In many of the large towns in England, and perhaps here also, numbers of so-called "maternity homes" are springing up into which women are taken for the purpose of their confinement. These places are usually presided over by a woman who is protected by a C.M.B. diploma, and either she or her staff conduct the labour. The "home" is frequently nothing more than an ordinary poorly furnished house, and no medical aid is solicited unless something goes wrong. I have frequently seen grave cases of puerperal sepsis in such places, many of which are none too clean, and where I have no doubt that far more "obstetric meddling" goes on than is conducive to the good of the patient.

It is one thing to train a woman for the C.M.B., but it is another to educate her in the proper equipment and management of a nursing home, as I have pointed out in a recent letter to THE LANCET.[1] A remedy lies in the *registration and periodical inspection of all nursing homes where maternity patients are taken.* Reputable institutions would welcome the recognition, whilst less desirable places would automatically disappear.

THE "EXTERN" MIDWIFERY CHARITIES.

That it is possible to prevent puerperal sepsis, given the necessary personnel and care, even *in the homes of the very poor*, is shown by the annual reports of the various extern midwifery charities. Recently I have perused the annual reports of the Rotunda, Liverpool, Manchester, Sheffield, and other maternity "extern" departments, and it is very refreshing to note the low incidence of maternal morbidity which attends the extern midwifery practice of the large hospitals in these centres. At my own hospital, the General Hospital, Birmingham, an extern midwifery department was opened last year. The "district" comprises the very worst slums in the city and is under the charge of my assistant, Mr. A. B. Danby, an obstetric house surgeon, a maternity sister and two trained nurses, and the students of the hospital. The maternal morbidity based on the B.M.A. standard is 1·2 per cent.

CHART 3.



Deaths from puerperal sepsis in England and Wales per 1000 births from 1912 to 1922.

---

[1] THE LANCET, 1923, ii., 1278.

for the year, a very satisfactory figure when consideration is taken of the patients' surroundings and the absence of most of the various obstetric luxuries which are sometimes thought essential for the prevention of sepsis. Most of the usual obstetric complications have been encountered, and I think that the main factor in the prevention of sepsis has been the care bestowed in the antenatal clinic.

ANTENATAL WORK.

There is no doubt about the importance of careful routine antenatal work under proper medical supervision as a factor in preventing puerperal sepsis. In the "extern" clinic at the General Hospital, Birmingham, every pregnant woman is examined at least once towards the end of her pregnancy by the honorary assistant obstetric officer. Malpositions are then corrected, the pelvic and abdominal measurements noted, and a swab taken from the cervical canal. Should streptococci be isolated from the latter, an autogenous vaccine is prepared and administered to the patient before the onset of labour. Careful notes are taken by the obstetric dressers on separate case-sheets for each patient, and these are filed for reference when labour commences. The actual labour is attended by the obstetric dresser, supervised by the maternity sister or one of her staff. It is the duty of the nursing staff to impress upon the student the antiseptic ritual as applied to obstetric practice in domestic surroundings, and also to prevent unnecessary vaginal examinations. As a rule one examination only is permitted during labour. The nursing staff attend with the students during the puerperium and take the usual steps to prevent infection after labour. In other words, it is the general aim to impress upon the students the fact that labour is a physiological and not a pathological process, and that pathological complications are to be dealt with before rather than during labour.

It is not to be expected that the knowledge, care, and experience requisite for efficient antenatal work can be exhibited by midwives with their brief period of training. The responsibility should not be shouldered by them, and I hope that the day may come when every prospective mother will have the advantage of a careful examination by a medical practitioner before her labour, even though a midwife actually officiates at the latter. What can be accomplished in the prevention of sepsis in the "extern" districts of hospitals should with some organisation be possible for other members of the community.

SPECIALISM FOR THE GENERAL PRACTITIONER.

Is it too much to hope for the evolution of "practitioner obstetricians," specialists in their own sphere, who in the area where they practise are responsible for the obstetric work of their district, and who do nothing else? Such obstetricians should receive generous remuneration from the State Insurance funds, and in addition to their own midwifery practice should act as supervisor of the midwives' cases in the same area. Surely by means of coöperation and coördination amongst practitioners such a step is possible.

The general practitioner with his multifarious duties would probably be only too glad to relinquish the additional responsibilities and trials of a large obstetric practice. General practice and midwifery do not easily assimilate, and the busy practitioner is, I think, to be congratulated on the fact that taking all the difficulties into consideration his results are as good as they are.

AUTO-INFECTION.

I wish in the next place to direct your attention to the consideration of an aspect of the problem which appears to be somewhat neglected. I refer to the question of auto-infection. When "puerperal fever," so-called, occurs, the tendency is generally for mutual recrimination to take place between the doctor, the nurse, and the patient's relations, and in the end I am afraid that the doctor is as often as not saddled with the whole blame for the débâcle. Although no doubt a large amount of infection is introduced from without, or carried up to the cervix from the vulva or perineum by the examining finger, I am not prepared to admit that the onus of infection is by any means always to be laid at the hands of the medical or nursing professions.

During the last few years I have repeatedly been asked in consultation to see patients where the doctor and nurse have both emphatically informed me that no vaginal examination has ever been made, and I believe them. In many cases, in fact, the child has been born before the arrival of any assistance, and yet puerperal streptococcal septicæmia has occurred. Where and how has the infection arisen? Had the doctor been so unfortunate as to use forceps in one of these cases, the blame would naturally have been laid at his door. That auto-infection does occur was recognised by Semmelweiss in 1861, who stated, "In rare instances the decomposed animal organic material which causes child-bed fever when absorbed is produced in the patient herself." Ahlfeld and Kaltenbach (1883–89) first put forward the suggestion that pathogenetic bacteria are present in the lower genital tract of many healthy pregnant women and that they may cause puerperal infection. A considerable amount of work has been done since, both with regard to the bacteriological investigation of the vulva and vaginal secretions during pregnancy, and of the lochia after labour. To a certain extent the conclusions are contradictory. Generally speaking, the weight of evidence is in favour of streptococci, both hæmolytic and non-hæmolytic, being present in varying proportions.

Whitridge Williams, however, after carefully sifting the evidence for and against auto-infection, expresses himself in the following terms: "In the first place, it appears that the vaginal secretion of normal healthy pregnant women does not contain streptococci which grow upon ordinary agar. On the other hand, the preponderance of evidence indicates that in a varying proportion of patients it does contain streptococci which grow readily in glucose bouillon. Furthermore, it is probable that the incidence of the latter depends in great part upon the personal cleanliness of the patient; and finally there is no evidence that the presence of such streptococci plays any part in the production of puerperal infection." This last statement is based upon the observations that in cases where streptococci have been demonstrated the puerperia have subsequently proved to be afebrile.

In the antenatal clinic at Birmingham General Hospital the taking of a swab from the cervix is part of the routine examination of patients. When streptococci are isolated the women are kept under close observation, and a research is at present in progress to ascertain whether the cocci tend to disappear as the pregnancy advances and whether they can be detected subsequently in the lochia.

Bacteriological Results in 50 Swabs.

The bacteriological results recorded in the last 50 cervical swabs by my assistant, Mr. A. B. Danby, and Dr. W. T. Hillier, bacteriologist to the hospital, are as follows:—

Organisms.	Number.	Per cent.
None on culture or film	3	6
,, ,, but + to film	27	54
,, film but culture +	3	6
Streptococci on culture	5 } 7	10 } 14
,, film	2	4
Staphylococci on culture	18	36
,, film	7	14
Diplococcus on film (Gram +)	1	2
Coliform bacilli on culture	2	4
,, ,, film	10	20
Gram + bacilli on culture	3	6
,, ,, film	30	60
Diphtheroid bacilli on culture	2	4
,, ,, film	15	30
Sarcinæ bacilli on culture	3	6
,, ,, film	1	2

Inasmuch as the puerperia in the extern patients have been afebrile in 98·6 per cent., it appears probable that the streptococci isolated are non-pathogenic.

No definite conclusion, however, can be reached until the investigation has been in progress over a long period and many hundreds of cases have been observed.

Attempts have been made from time to time to demonstrate that the streptococcus of virulent puerperal infection—i.e., true "puerperal fever"—is specific. Krönig, Williams, and Schotmüller, for example, have isolated an anaerobic streptococcus which is designated *Streptococcus putridus*, and which they affirm is more frequently concerned in the production of puerperal infection than the ordinary aerobic group. Mackey, on the other hand, claims to have isolated an organism of such definite morphological appearance that he associates it always with puerperal infection, and is able to pick it out from streptococci obtained from other sources. He calls it *Streptococcus puerperalis*. The work awaits confirmation, and in the meantime it appears advisable to regard all streptococci in the genital tract of the parturient woman as potential sources of infection.

Infection by Blood-stream.

I turn to another question—viz., can puerperal infection arise from a septic focus elsewhere in the body by infection of the uterus via the blood-stream? The question is prompted by the following three cases, which I select as examples bearing on the point.

Case A.—A primipara of good social position had suffered from chronic inflammation of the maxillary antrum for two years before pregnancy occurred. During the early months of gestation suppuration in the antrum appeared to be probable, but operation was deferred owing to the coexisting physiological condition. Labour took place at the patient's home under ideal conditions. A senior and experienced practitioner was present, with a fully-trained nurse. No vaginal examinations were made either before, during, or after labour, and the placenta was expelled naturally from the vagina. The patient had not previously suffered from any vaginal discharge or pelvic symptoms. Pyrexia occurred a few days after labour, and owing to coexisting headache, &c., it was thought that the maxillary antrum might be the cause of the high temperature. A surgeon was called in and he drained the antrum, evacuating pus. The pyrexia did not subside, however, and a complete bacteriological investigation was then made. Three swabs from the uterus and the blood all showed the same streptococcus. The urine was sterile. The weak link in the chain is that the ear and throat surgeon did not have the pus from the antrum examined bacteriologically.

Case B.—A multipara in the heart of the country in the Midlands was delivered naturally at her cottage of a healthy full-term child and placenta before the arrival of either practitioner or district nurse. Her husband only was present at the time. The previous pregnancies had been normal and the puerperia uncomplicated. The patient had suffered from chronic otitis media for some years. Septicæmia developed within three days from the confinement. A uterine swab and also a blood culture showed a streptococcus. The patient died in hospital 14 days later with a cerebral abscess. At the autopsy the uterus presented the typical signs of septic endometritis and metritis.

Case C.—A primipara of good social status during the later months of her pregnancy developed nephritis. Albumin and streptococci were present in the urine. Labour took place in a first-class nursing home under the supervision of a skilled consulting obstetrician. In spite of all care and precautions, streptococcal septicæmia followed the labour with a fatal result. This case is, of course, open to the criticism that owing to the presence of streptococci in the urine an ascending infection of the genital tract may have occurred, in spite of the precautions taken.

Examples such as I have cited naturally direct thought in one direction. Apart altogether from obstetrics we are familiar with the results of a chronic bacteriemia. Instances may be mentioned of acute pyelitis supervening upon a suppurating tonsil, chronic pyæmic abscesses occurring in a patient with a suppurating maxillary antrum, or iritis relieved by the extraction of carious teeth, with alveolar sepsis.

It is not a great step, therefore, to trace the development of uterine sepsis in the placental site of a patient who is the subject of a chronic suppurating focus. It is reasonable to suppose that streptococci under such conditions may take a fresh lease of life both in virulence and morphological characteristics. We have only to compare the activities of the coliform group of bacteria under similar circumstances. That bacteria are brought to the uterus by the blood-stream has been shown conclusively by Whitridge Williams, who, in fatal cases of influenzal pneumonia, demonstrated the presence of chains of streptococci in arterioles *making their way through the uterine musculature to the decidua*. Czemetschka and Burchardt also have reported the presence of pneumococci in the uterine lochia, as a manifestation of a general septicæmia originating from a focus outside the generative tract.

It is not possible to go further at this stage. In passing, however, may I draw attention once more to the very high mortality-rate from puerperal sepsis in all countries in the year 1920, and raise the question as to whether some of the mortality may not have been a blood infection and related to the influenza epidemics? The practical consideration that evolves from the discussion is, to my mind, the importance of treating carefully and thoroughly any septic focus that may be present during pregnancy, rather than deferring the same until a later period.

Treatment of Puerperal Sepsis.

I am afraid that I have left very little time for a discussion of therapeutic methods. My excuse is that the best treatment of puerperal sepsis is its prevention. I do not propose to enter into a full account of all the various measures that have been vaunted from time to time, but simply to refer to the methods which in my hands have given the best results. At the outset it must be remembered that many cases undoubtedly will recover whatever treatment is adopted, and, on the other hand, some patients are lost in spite of the application of every measure which we know to-day.

General Principles.

In order to obtain the best results, however, certain principles must be adopted. The first of these, in my opinion, is that treatment must be started at the earliest possible moment. It is no good waiting until the symptoms have persisted for several days in the hope that the temperature and pulse-rate will subside. If this is the case, all well and good, but if the contrary is true valuable time has been lost and the chances of the patient's recovery jeopardised. I know the argument will be raised that there are other causes of pyrexia than puerperal sepsis, and that in many cases alarming symptoms subside naturally without producing any further trouble. This is so. I prefer, however, to regard any rise of temperature to 101° F. with a corresponding increase of pulse-rate to 110 or over as a manifestation of sepsis until the contrary is proved, and under these circumstances I always counsel the bacteriological investigation of the uterine cavity by examination of a swab.

The second principle is that it is unwise in the interests of the patient to differentiate between sapræmia and septicæmia, or again to depend upon the superficial characteristics of the uterine lochia. The former in practice merges so easily into the latter, and both foul-smelling, purulent, and serous discharges equally may contain dangerous streptococci that the issue is only obscured if any reliance is placed upon the same in forming a diagnosis.

The third important factor is that the patient shall be in surroundings where efficient nursing is possible, and where it is carried out by a properly trained nursing staff. It is perhaps impossible under all circumstances, but my own practice, whenever feasible, is to transfer the case to hospital or nursing home. As to the details of actual treatment, the measures adopted should, in my opinion, be both local and general. I always adopt the same routine which is as follows:—

Local Treatment.

The patient is anæsthetised and placed in the lithotomy position. The external genitals are shaved if this has not already been done, and thoroughly cleansed with a solution of sodium hypochlorite. The preparations I personally use are either "Milton" or

Burroughs and Wellcome's "Tolamine." The vagina is next swabbed out and finally the cervix and uterine cavity, a large quantity of hypochlorite solution being used during this procedure. The uterine cavity is then *lightly* curetted and a large double drainage-tube introduced into the uterine cavity and carried to the fundus of the organ. This tube is sufficiently long for the ends to be brought outside the vulva, and is used for repeated irrigation of the uterine cavity with the hypochlorite solution. The uterus is washed out every two or three hours by the nurse in attendance, who syringes the solution through the tubes.

I am fully aware that this local treatment of the septic uterus has been subjected to criticism. The curette, whether it be sharp or blunt, has been denounced as an instrument which conveys the infecting organisms deeper into the uterine tissues and opens up fresh channels of infection. I can only say that *curettage in the constant presence of a powerful antiseptic* has not, in my personal experience, ever done one atom of harm, and further, it has on several occasions undoubtedly done good by removing retained decomposing portions of placenta or membrane. It is also only right to state that constant or frequently repeated irrigation of the septic uterus is also not generally adopted. Gordon Luker, in fact, in a recent communication, observes that at Queen Charlotte's Hospital he has not observed any particular advantage from the adoption of Carrel-Dakin methods, and in recent cases has been devoting less and less attention to the local uterine conditions. I am entirely open to conviction on these two debatable points, but as long as the results of treatment remain satisfactory in my hands I do not feel inclined to change my technique. The important point, I believe, is that curettage *must be light*, and it *must be associated with constant irrigation* of the uterus. If *heavy* and *employed alone it is undoubtedly dangerous.*

Up to date I can claim a consecutive series of 62 cases of severe puerperal sepsis with only five deaths. In this series a uterine swab showed infection with a streptococcus either alone or as a mixed infection, and no case is included in which the pulse-rate did not reach 120. A further point is worth placing on record, and that is that two of the five fatal cases were neither curetted nor irrigated. Serum- and vaccine-therapy alone was employed.

One other remark in connexion with irrigation: if it is adopted at all no half measures will suffice. The vaginal douche, or the single intra-uterine douche, only washes away such discharge as happens to be present at the moment and can in no sense be curative.

General Treatment.

The general treatment of a septicæmic patient in my hands resolves itself into the application of the following measures: (*a*) Serum-therapy; (*b*) autogenous vaccines; (*c*) intravenous "acriflavine" with (*d*) a concentrated and nutritious diet, and a liberal allowance of alcohol. Since the publication of Luker's paper I am testing the value of intravenous and intramuscular solutions of quinine bihydrochloride as recommended by him, but cannot as yet express any considered opinion, as the method is too recent. Intravenous injections of Witte's "peptone" have not, in my hands, proved of sufficient value to replace or add to other measures. Anti-streptococcic serum is best given, I think, intravenously, in large doses, with an equal quantity of saline as advised by Leith Murray. I administer an initial dose of 50 c.cm. of stock serum with 50 c.cm. of normal saline and 1 c.cm. of serum from a freshly-killed guinea-pig. The latter is added in order to introduce "complement" as suggested by Leith Murray. On each of the two following days 30 c.cm. of serum is given with an equal amount of saline, the injection on each occasion being administered very slowly. Autogenous vaccines are used in conjunction with other measures, but I should not care to rely upon vaccine-therapy only in a severe case of puerperal systemic infection. I cannot claim to have witnessed any very dramatic results in acute cases of sepsis treated only by vaccine, and on the other hand, I can recall three deaths. Perhaps I have been unlucky.

Acriflavine in a strength of 1 in 250 in normal saline I have now used for some years in the treatment of puerperal sepsis, and I think that it does good. In severe cases it is given intravenously in doses of 20 c.cm. morning and evening. In a few instances the daily injections have been continued for over a fortnight until the patient's skin has assumed a lemon tint. The urine in these cases has shown clear evidence of the treatment. One patient was treated solely by this method and made an excellent recovery, although the infection originally appeared to be of a very virulent type. The disadvantage attached to these repeated injections is the discomfort attached to the treatment. Patients often complain very bitterly about the continued punctures, especially after several days. I think that I have said sufficient to render it evident that we possess no one specific in dealing with severe sepsis once the infection has secured a firm hold of the individual. As I have noted previously, cases occur where the infecting agent is so virulent that the patient is dead almost before treatment can be instituted. I remember one such instance some years ago. I was called to see a primipara confined 24 hours previously who had a temperature of 104° F. She was covered with an erythematous rash and died the following morning within 48 hours of the labour. A diplococcus, apparently the pneumococcus, was present in the blood.

In conclusion, therefore, may I repeat the words that I have already used—viz., that with our present knowledge, it is far better to prevent puerperal fever than to attempt its cure. Whilst acknowledging the debt we owe to therapeutics in reducing the mortality from puerperal sepsis, the problem of prophylaxis appears to offer less difficulties in the attainment of success.

THE TREATMENT OF SEVERE GASTRIC AND DUODENAL HÆMORRHAGE.[1]

By ARTHUR F. HURST, M.D. Oxf., F.R.C.P. Lond.,
PHYSICIAN TO GUY'S HOSPITAL.

The Mortality from Gastric and Duodenal Hæmorrhage.

I believe that hæmorrhage from gastric and duodenal ulcers is far less often fatal than is generally supposed. I have never had a case under my care in which death resulted, although I have only once had to call in the aid of a surgeon to save the patient's life. Dr. J. J. Conybeare has investigated the records of all post-mortem examinations on cases of fatal hæmorrhage from an ulcer of the stomach and duodenum in the absence of cirrhosis of the liver, which occurred at Guy's Hospital between the years 1911 and 1920 inclusive. The total number was only 23, which is equivalent to 2·6 deaths a year, if allowance be made for the fact that no post-mortems were made on 12 per cent. of patients dying in the hospital. The deaths from this cause accounted for no more than 0·37 per cent. of the 6302 autopsies performed during the ten years. Only 13 out of the 23 died from hæmorrhage without having undergone some previous operation. As about 600 cases were admitted during this period for hæmorrhage from an acute or chronic ulcer, the mortality of severe gastric and duodenal hæmorrhage is only about 2·5 per cent.

Medical Treatment of Hæmatemesis.

The most important factor favouring the cessation of hæmorrhage from the stomach or duodenum is complete immobility. Immobility of the patient keeps the blood pressure down; immobility of the stomach and duodenum prevents a newly-formed clot from being dislodged. Distension of the stomach and duodenum removes the support of surrounding tissues from the bleeding vessels and keeps the aperture in its wall widely open. An empty, contracted stomach, like an empty, contracted uterus, has no lumen, and its effect on hæmorrhage is the same. It reduces the flow of blood through its blood-vessels, and it controls the hæmorrhage by the direct pressure of the opposite wall of the viscus on the bleeding surface.

---

[1] A contribution to a joint discussion at the Medical, Surgical, and Therapeutic Sections of the Royal Society of Medicine. A short abstract of this paper and a report of the discussion appeared in The Lancet of March 15th.

Immobility of the patient is secured by keeping him quiet in bed, reassuring him about his condition —a very important point, too often neglected, especially in hospital—and giving him sufficient morphia by repeated subcutaneous injections to keep him drowsy and prevent the mental and physical restlessness which are otherwise likely to be present. Atropine should be added to the morphia in order to inhibit as much as possible the secretion of gastric juice.

Immobility of the stomach and duodenum is secured by giving the patient neither food nor drink by mouth. Complete starvation should be continued until, so far as can be ascertained, no bleeding has occurred for 48 hours. The ordinary strict treatment of an ulcer with diet, alkalies, belladonna, and olive oil should then be begun. During the period of starvation the mouth should be kept scrupulously clean; there is then no danger of parotitis. As much dextrose solution as possible should be given by rectum, and if the mouth is parched and the patient shows signs of being dehydrated, saline solution should be injected subcutaneously. There is no object in giving ice to suck. To the stomach blood is as much a food as any other protein, so that gastric juice is secreted and peristalsis occurs as actively as with an ordinary meal. When the hæmorrhage is severe, the rapid distension of the stomach results in its more or less complete evacuation by hæmatemesis. This is followed by contraction of the stomach, which may cause the hæmorrhage to cease. Smaller quantities are evacuated in the ordinary way through the intestines and give rise to melæna. But when the hæmorrhage is severe and continues after hæmatemesis has occurred, or when in spite of its severity it is not sufficiently rapid to cause the sudden distension which results in its ejection by mouth, death may result unless steps are taken to empty the stomach. It is common knowledge that uterine hæmorrhage can almost always be arrested by emptying the uterus and causing it to contract; it is less widely known that similar treatment for severe gastric hæmorrhage is almost equally effective.

A stomach-tube is passed just far enough for the end to reach beyond the cardia. This prevents any possibility of directly disturbing the bleeding surface. The stomach is now emptied; this can be most conveniently done by having the tube connected with a Senoran's evacuator. The stomach is next washed out with about 4 ounces of ice-cold water, and this is repeated over and over until the water which comes back is no longer blood-stained. Instead of water, 1 in 1000 ferric chloride solution,[2] also iced, can be used, as its styptic action may help to arrest the bleeding. When the last traces of water have been evacuated, a drachm of 1 in 1000 adrenalin chloride is poured into the stomach before withdrawing the tube. This may now gain access to the bleeding surface and cause the leaking vessel or vessels to contract. It is particularly likely to be effective in acute ulcers, and in the condition called gastrostaxis by Sir William Hale-White, in which there is general oozing, presumably from innumerable minute erosions. When given in the ordinary way by mouth, the adrenalin is so diluted by the contents of the stomach that the trace which reaches the bleeding surface must be quite ineffective. There need be no fear that the general blood pressure will be raised and that the danger of a recurrence of hæmorrhage will thereby be increased, as adrenalin given by mouth is not absorbed, and has no effect at all on the blood pressure.

Arrest of Hæmorrhage.

The complete evacuation of the stomach and the stimulation of the mucous membrane with ice-cold water result in firm contraction of the whole organ, and the hæmorrhage is almost invariably arrested if it is gastric in origin. Duodenal hæmorrhage also generally stops, because the duodenum has no longer to deal with blood mixed with acid gastric juice coming to it from the stomach, and both the iced ferric chloride solution and the adrenalin may now reach the ulcer. Hæmorrhage ceases when a firm clot has formed at the bleeding-point. The danger of recurrence depends upon the digestion of the clot by gastric juice, the secretion of which is called forth by blood just as it is by any other food. Consequently, it is essential to render the gastric juice inactive by neutralising as completely as possible all the free hydrochloric acid which is present. For this purpose alkalies must be given which do not, like sodium bicarbonate, stimulate the secretion of more juice after neutralising an equivalent amount of acid, or give off large quantities of carbon dioxide, which distends the stomach and stimulates peristalsis. Oxide of magnesia is almost ideal from these points of view, as it has four times the neutralising power of sodium bicarbonate, it is a comparatively feeble stimulant of gastric secretion, no gas is given off when it combines with acid, and it also acts as a mild aperient and so tends to prevent the severe constipation and resulting putrefaction of blood in the colon, which is the cause of the frequent pyrexia after a severe gastric or duodenal hæmorrhage. Calcium carbonate is also useful, as it has two and a half times the neutralising power of sodium bicarbonate, it does not stimulate the secretion of gastric juice at all, and it neutralises the acid so slowly that the gas given off dissolves in the water present as rapidly as it forms, so that no distension results. Possibly some of the calcium chloride produced may be absorbed and increase the coagulability of the blood. Bismuth carbonate has only one-third of the neutralising power of sodium bicarbonate and it causes the stools to be black, so it is best avoided, as the naked-eye examination is a rough indication as to whether the hæmorrhage is stopping.

Oxide of magnesia can be most conveniently given as emulsio magnesiæ (B.P.C.), each drachm of which contains 5 gr. of oxide. A mixture is made containing 30 gr. of prepared chalk to each ounce of the magnesia emulsion. An ounce of the well-shaken mixture is given as soon as possible after the hæmorrhage and then hourly during the day, and as frequently as the patient is awake during the night. This is continued until food is begun, when it can be replaced by the usual alkaline powders given half-way between the two-hourly feeds.

In all cases septic foci should be carefully looked for and thoroughly eradicated at an early stage of convalescence; if the ulcer is an acute one no other after-treatment is required.

At the earliest possible moment after a hæmorrhage, the patient's blood should be grouped and a donor should be found who can be summoned at an hour's notice any time during the day or night should transfusion become necessary. If this precaution is taken no patient should die as a result of hæmorrhage from an acute ulcer, or as a result of the general oozing from the mucous membrane in gastrostaxis. Fatal hæmorrhage from a chronic ulcer should also hardly ever occur, as in the most severe cases, where a sclerotic artery incapable of contracting has ruptured, transfusion should tide the patient over sufficiently long for it to be possible to deal directly with the ulcer by operation. The only inevitably fatal cases are the extremely rare ones, in which death occurs actually during the first hæmorrhage, generally owing to erosion of one of the main gastric or duodenal vessels.

The hæmoglobin percentage should be estimated at the same time as the blood is taken for grouping. Daily estimations should be made until the patient is obviously out of danger. When further hæmorrhage is suspected, although no hæmatemesis has occurred, an additional estimation should be made, as a fall in the percentage would confirm this and indicate the wisdom of washing out the stomach. On the other hand, if the hæmoglobin percentage remains unaltered or rises, it is clear that no further hæmorrhage has occurred. Transfusion should be carried out at once if the hæmoglobin percentage falls to 30.

---

[2] Daily lavage of the stomach with 1 in 1000 ferric chloride solution was the routine treatment for gastric ulcer recommended by Bourget, of Lausanne, 20 years ago.

Every practitioner may at any moment be called upon to treat a case of severe hæmatemesis. There are few conditions in which life and death depend so directly upon the treatment he adopts. I believe that a fatal result will be extremely rare if treatment on the lines I have laid down is carried out. It is perhaps necessary to point out that for its success to be assured the practitioner must be adequately equipped. He should have in his possession a stomach-tube with a Senoran's evacuator. He should have an accurate hæmoglobinometer, which he is in the habit of using for the diagnosis and control of his cases of anæmia. It is one of the instruments of precision which are easy to use, require very little time, and which ought not to be regarded as a specialist's toy, which nobody but the hæmatologist should be expected to use. There should also be at least one man in every district who can group a specimen of blood and carry out a transfusion. Only six months ago I found that there was nobody in a certain city with 50,000 inhabitants who could do this, and I wondered how many lives had been lost in consequence. Lastly, I hope the time is not far distant when London and every large town will have a list of blood donors, properly grouped, who can be called upon in emergencies, when no suitable relation or friend is available.

When the bleeding has stopped, the percentage of hæmoglobin quickly rises in most cases. In a recent case under my care it rose from 20 to 60 per cent. in 11 days. Iron given by mouth or subcutaneously does not seem to have much effect in hastening the blood regeneration, and arsenic is of still less use. When improvement is slow the patient should be transfused. This not only produces an immediate rise of between 5 and 10 per cent. of hæmoglobin, but it almost always stimulates the delayed blood formation. The general improvement in the patient's condition seems also to hasten the healing of the ulcer, which sometimes tends to be very slow in cases of this kind.

Indications for Immediate Surgical Treatment.

In view of the very small danger of death from hæmatemesis or melæna, it is clear that operation can very rarely be called for with the immediate object of arresting the hæmorrhage. Dr. Conybeare found that in seven of the thirteen cases of hæmorrhage from a gastric or duodenal ulcer, in which death occurred without previous operation at Guy's between 1911 and 1920, the ulcer producing the hæmorrhage was definitely of the acute type—five times in the stomach, once in the duodenum, and once in both stomach and duodenum. In none of the seven cases was there any history which would have justified surgical intervention at an earlier date. One patient had delirium tremens three months before death, and in two other cases the acute ulceration was associated with a lung abscess and gall-stones respectively. It may be safely concluded that in none of these seven cases would any operation on the stomach or duodenum have been successful in preventing death, even if undertaken at the time of the hæmatemesis. In only three of the six cases of chronic ulcer, which died from hæmorrhage apart from operation during the same period—or 0·5 per cent. of admissions from hæmatemesis and melæna—was there a history which could have distinguished them from the acute cases; in none but these could an operation have been reasonably undertaken with some hope of saving life. Quite apart from the very small danger of death from hæmorrhage —2 per cent. at Guy's—the immediate results of operation performed for its direct treatment are so unfavourable that I expect most British surgeons will be inclined to agree with American surgeons, who, according to Balfour, are now unanimous that "the danger of succumbing to hæmorrhage is less than the danger of operation during hæmorrhage."

I believe that the only indication for operation in the acute stage is the occurrence of severe and persistent hæmorrhage in an elderly individual with a long history pointing to the presence of a chronic ulcer, whose arteries are so degenerated that they are unlikely to contract sufficiently for satisfactory plugging by thrombosis.

I have only once found it necessary to have an operation performed on account of hæmorrhage from a gastric or duodenal ulcer. I had advised the patient, a man of 60 with severe arterio-sclerosis, to have a gastro-enterostomy the first time I saw him some months before his hæmorrhage, as he had a very long history of duodenal ulcer, which had led to obvious pyloric obstruction. He refused to submit to surgery, and continued to wash his stomach out two or three times a day as he had done for years. He then had a severe hæmorrhage which was repeated at the end of a week's starvation, when I saw him for the second time. I advised immediate operation. The next morning Sir Berkeley Moynihan found an enormous duodenal ulcer producing pyloric obstruction; he performed a gastro-enterostomy and cut off the blood-supply to the ulcer by overlapping sutures round it. The patient did very well, and died four years later from pneumonia without having had any recurrence of gastric symptoms.

I have also once had to recommend operation on a man who bled repeatedly from a jejunal ulcer, which had developed as a result of a gastro-enterostomy performed the same time as a perforation of a duodenal ulcer was sutured. A jejunostomy was made and the hæmorrhage ceased, but death resulted from peritonitis owing to the jujunum tearing away from the abdominal wall. All his subsequent misfortunes would probably have been avoided, if the surgeon had been content with suturing the perforation without performing gastro-jejunostomy at the time of the first operation.

Is Hæmorrhage in Chronic Ulcer an Indication for Subsequent Operation?

Before deciding whether the danger of a recurrence of hæmorrhage should be regarded as an indication for operation when the patient has recovered from his acute symptoms, it is necessary to see what the results of surgery are in cases of ulcers which have previously bled, and how frequently hæmorrhage occurs after operations on patients who have never before had hæmatemesis or melæna. According to Balfour, hæmorrhage occurred after operation at the Mayo Clinic in 13 per cent. of cases of ulcer (83 duodenal and 17 gastric) with a history of previous hæmorrhage, but only in 0·9 per cent. of cases with no previous hæmorrhage. This may be regarded as the minimal risk, which requires correction by such statistics as those of Hohlbaum from Payr's University Clinic in Leipzig in which the after-history is taken into account, in order to get an accurate idea of the average risk. Hohlbaum reported in 1922 that no less than 20 per cent. of cases in which a gastro-enterostomy was performed for duodenal ulcer were followed by severe and occasionally fatal hæmorrhage, either immediately or months or even years later. As most of the cases in which hæmorrhage occurred were in patients who had previously bled, the operation is now no longer performed at Leipzig for hæmorrhagic cases. Of the nine Guy's cases between 1911 and 1920, in which death followed hæmorrhage from an ulcer and in which an operation had been previously performed, only two had suffered from hæmorrhage before the operation. In one of these death occurred from hæmorrhage the day after a gastro-enterostomy for a duodenal ulcer, and the other from hæmorrhage from a gastric ulcer three years after the excision of an earlier gastric ulcer. In all the other cases the first hæmorrhage occurred after the operation. The hæmorrhage took place respectively seven days, eight days, and five years after a gastro-enterostomy for gastric ulcer, six days after a gastro-gastrostomy for gastric ulcer, and six weeks after an ileo-sigmoidostomy for gastric ulcer. One of those who died after a gastro-enterostomy had had an ileo-sigmoidostomy performed two years earlier. Lastly, one patient died of hæmorrhage 14 days after the suture of a perforated chronic pyloric ulcer, and another nine months after suture of a perforated chronic gastric ulcer. As about 900 cases had undergone operation for gastric or duodenal ulcer during the period under review, and nine such cases died of hæmorrhage, the mortality from hæmorrhage after operation is approximately 1 per cent.

I am able to supply further information on this subject from the statistics of New Lodge Clinic. Out of 60 consecutive patients with gastric or duodenal ulcer admitted to the clinic, who had not previously undergone any operation, five of the 16 gastric cases and eight of the 44 duodenal cases had had hæmatemesis or melæna or both, together making 21·6 per cent. Nine of these patients had an operation subsequently performed for their ulcers on account of pyloric or hour-glass obstruction, and one because of failure of medical treatment; the only one who had previously had a hæmorrhage had another severe hæmorrhage the day after the operation.

During the same period 25 patients were admitted for symptoms which had followed an operation performed for duodenal ulcer. Among the 16 of these who had not previously bled, one had a hæmorrhage three days and another four days after the operation, a third had hæmatemesis three years later, and a fourth had repeated severe hæmorrhages from a jejunal ulcer, which had finally to be excised. The remaining nine had had hæmatemesis or melæna before the operation, and in no less than seven it recurred with equal or greater severity afterwards; in two cases a bleeding jejunal ulcer was still present after two additional operations had been performed. Thus, out of 26 cases of hæmatemesis or melæna no less than 11, or 42 per cent., occurred after operation, and of these four had not previously bled. These figures show that the liability to hæmorrhage is just as great after an operation has been performed for a gastric or duodenal ulcer as after medical treatment, whether the patient has already had a hæmorrhage or not.

Is the Danger of a First Hæmorrhage in Chronic Ulcer an Indication for Operation?

The supposed liability to hæmorrhage and the supposed danger of the latter to life are often used as arguments in favour of the operative treatment of gastric and duodenal hæmorrhage. Neilson has investigated the after-history in a series of 182 patients from Prof. Faber's clinic in Copenhagen, who were diagnosed with a fair degree of certainty as suffering from ulcer. An operation was performed on 42 of them between one and 21 years later, but never for hæmorrhage. The remainder were traced for between two and a half and 19 years; of these 16 had died, but only two, or less than 1 per cent. of the whole series, from hæmorrhage.

Dr. Conybeare's investigations on the history of the 23 fatal cases of gastric and duodenal hæmorrhage, which occurred at Guy's Hospital between 1911 and 1920, throw further light on this question from a different point of view. Of the six deaths from hæmorrhage from a chronic ulcer one gastric and one duodenal case had a history of only six and eight weeks respectively, and one patient, an old man of 74, who died from hæmorrhage from a chronic duodenal ulcer whilst in hospital for a fractured femur, had never suffered from indigestion. Only two patients with a long history of indigestion died as a result of hæmorrhage from a chronic gastric ulcer, and one from a chronic duodenal ulcer without having previously undergone any operation; of these the duodenal case and one gastric case had had previous attacks of hæmatemesis and the duodenal case had had melæna.

We may conclude that only two patients with chronic gastric ulcer and one with chronic duodenal ulcer died of hæmorrhage in Guy's Hospital in the ten years between 1911 and 1920, who had had symptoms which should have made a correct diagnosis possible before the occurrence of fatal hæmorrhage, and whose lives might therefore have been saved if an operation had been performed sufficiently early. But when it is remembered that during the same period two patients with a history of hæmatemesis died from hæmorrhage after operation, and no less than seven whose ulcers had never bled before died from hæmorrhage after operation, it is clear that the number who actually recovered under medical treatment, but who might have died after operation if surgery had been the routine treatment for all cases diagnosed as ulcer, would more than have counterbalanced the death of these three patients who might possibly have been saved by an earlier operation.

The statistics collected by Neilson from Faber's clinic are the only previously published ones which supply the same kind of information as Dr. Conybeare's Guy's Hospital statistics, and the conclusions which can be drawn from them are exactly the same. Between 1897 and 1915 528 patients were diagnosed as having a gastric or duodenal ulcer. During the same period ten patients died as a result of hæmorrhage from an ulcer, but four of them had had no digestive symptoms prior to the fatal hæmorrhage. Four others had had slight pain, nausea, or vomiting within the previous six months, but not before; the ninth had had occasional epigastric pains, to which he "had not paid attention" for a couple of years, and the last had had occasional attacks of "gastric catarrh" for six years. In none had there been any previous hæmorrhage, and in none had the symptoms been of such a nature that a definite diagnosis of ulcer could have been made. It is extremely doubtful whether the most enthusiastic surgeon would have operated on more than one or two of them had he seen them at any time before their admission for hæmorrhage.

In view of these results it seems to me that neither the occurrence of hæmorrhage in the past, nor the danger of hæmorrhage in the future in a patient with an ulcer which has not previously bled can be regarded as in any way pointing to the desirability of surgical rather than medical treatment for a chronic ulcer. In my opinion the only definite indications for surgery are hour-glass contraction and pyloric obstruction, neither of which should ever occur if the diagnosis is made as early as it should be, the treatment is sufficiently strenuous and prolonged, all septic foci are thoroughly eradicated, and proper after-treatment is instituted.

LEBANON MENTAL HOSPITAL.—The annual general meeting of the hospital, situated at Asfuriyeh, near Beyrout, Syria, will he held at Caxton Hall, Westminster, on Tuesday, June 3rd, at 5 P.M. The chair will be taken by Dr. E. W. G. Masterman.

EAST END MOTHERS' LYING-IN HOME.—At the annual meeting held at 46, Park-street, London, W., on May 21st, Dr. Owen Lankester, on behalf of the committee, made a presentation of an illuminated address and a silver cake basket to Dr. M. Cursham Corner, retiring after more than 40 years' service as medical officer to the home. Dr. Corner stated that when the home was first opened it was the only one of its kind in East London for poor mothers. Mrs. Alfred Lyttelton said that, in going round the home, she had been struck by the fact that the mothers of first babies looked happy and at peace, while the mothers of families often appeared anxious and harassed because they were worrying about the other children at home. She pleaded that help should be forthcoming to enable the home to give to poor mothers the skilled attention and some of the comfort and quiet enjoyed by those in happier circumstances. Mr. W. McAdam Eccles, who had visited the home on behalf of the King Edward Hospital Fund, remarked that during last year, out of 1020 mothers delivered in the home, there was only one maternal death (from accidental hæmorrhage) and not a single death among 1262 mothers delivered on the district. He extended a welcome to Dr. Corner's successor, Dr. W. H. F. Oxley.

THE INORGANIC CONSTITUENTS OF THE BLOOD

IN CERTAIN PATHOLOGICAL CONDITIONS.

By O. L. V. DE WESSELOW, M.B. OXF., F.R.C.P. LOND.,
CHEMICAL PATHOLOGIST, ST. THOMAS'S HOSPITAL.

(*A Report to the Medical Research Council.*)

THE inorganic salts of the plasma may be regarded as constituting a Ringer's solution, which must presumably be kept at a fairly constant composition if the life processes are to continue. In this solution circulate the various protein constituents of the plasma, food products in their passage to the tissues, and waste products derived from tissue metabolism. Of recent years these food and waste products have been the subject of numerous investigations: the sugar and urea contents of the blood have, for instance, been extensively studied, and their estimation now plays an important rôle in clinical medicine. The inorganic constituents have attracted less attention. There are, of course, important exceptions to this statement, such as the bicarbonate content of the plasma, which, owing to the development of a simple and rapid method of estimation by Van Slyke, has come to possess a very definite significance in medicine, but it may be safely stated that our knowledge of the variations in the inorganic constituents of the blood is at a lower stage of development than our knowledge of the bodies mentioned above.

The principal reason for this position is to be found in the lack of methods of estimating the inorganic constituents, suitable for clinical application and also adequately accurate. The older methods were laborious, and, in addition, if anything approaching a complete inorganic analysis was attempted, necessitated the use of larger quantities of blood than could be conveniently or justifiably removed from human patients. Simpler and more rapid methods are now available, and it is possible to determine the more important acid and basic radicles in less than 40 c.cm. of blood, a quantity readily obtained by venipuncture.

In this paper some of the results of more than 60 analyses of certain inorganic constituents of the blood are detailed. The material included patients suffering from diabetes, nephritis, toxæmias of pregnancy, decompensated cardiac lesions, and other conditions in which deviation from the normal might reasonably be expected to occur. The substances estimated were: in plasma, chloride, phosphate, and bicarbonate, and in the corresponding serum, sodium, potassium, and calcium. The plasma was separated rapidly by centrifuge with the usual precautions, and the serum removed from the clot within two hours of withdrawal of the blood. Magnesium was not estimated, partly owing to lack of time, and partly to the fact that, in the few papers which have appeared on the subject, no significant variations from the normal have been recorded. Sulphates also were not determined, though Denis has recently shown that in certain types of renal disease considerable accumulations of sulphate may occur in the blood. The importance of estimating as many inorganic constituents as possible in any sample of blood must be recognised, since, as will be seen later, variations in one body may be only capable of interpretation in the light of variations in another.

Methods Employed.

CO_2-combining power of plasma (bicarbonate), Van Slyke.

Phosphate content of plasma, Bell–Doisy.[1]—For this estimation the plasma was removed from the corpuscles within 30 minutes of withdrawal of the blood, minimal amounts of oxalate being used to prevent coagulation. It may be pointed out that the alkaline sulphite solution employed in the method should be prepared at frequent intervals, since otherwise the terminal reduction is unsatisfactory.

Chlorides of plasma, Donleavy–Van Slyke,[2] estimated in the same plasma as the bicarbonate.—The method is known to give somewhat high results, and the figures given, though comparable *inter se*, are not to be accepted as absolute values.

Calcium of serum, Kramer and Tisdall.[3]

Potassium of serum, Kramer and Tisdall.[4]—The serum for this determination was removed from the clot within two hours of withdrawal of the blood. Unless this precaution is observed high values are obtained, owing to escape of potassium from the corpuscles, which are exceedingly rich in this element. Serum left in contact with the clot for as short a time as five hours sometimes shows a definite increase in its potassium content, and in 24 hours the potassium content may double. In a few instances, in spite of the greatest care in adding the cobalti-nitrite reagent to the serum, a fine filmy precipitate, presumably protein, develops, and is detected during the final solution of the potassium cobalti-nitrite precipitate in N/50 permanganate. This precipitate is not due to any ageing of the reagent, but appears to be due to some peculiarity of the serum. Under these conditions the final readings are high, and the determinations were discarded.

Sodium, Kramer and Tisdall.[4]—All precipitates were dried to a constant weight at 110°. Though good results (within ± 5 per cent.) were obtained with simple solutions containing sodium, the results in serum were not entirely satisfactory. Considerable difficulty was at times experienced in drying the crucibles to a constant weight, especially when the same crucible had been used, as suggested by the authors of the method, for a series of determinations. The thick layer of precipitate under these conditions is very difficult to dry thoroughly. On the other hand, unless the filter is adequately clogged, low values are obtained. When any difficulty was found in obtaining a constant weight the results were not accepted.

Typical findings are given in the following tables. The sodium, potassium, calcium, and urea (when determined) are given in milligrammes per 100 c.cm., phosphates as mg. of phosphorus, and chlorides as mg. NaCl per 100 c.cm.; CO_2 as c.cm. per 100 c.cm. of plasma.

Normal Cases.

The findings in the normals (Table I.) call for no extensive comment. The figures obtained are in accordance with those of other workers. The chief points of interest are (1) the relative excess of basic over acid radicles, and (2) the large proportion of the total base which is in combination with hydrochloric acid. As regards the first of these, the excess of base is, presumably, to a very large extent in combination with the plasma proteins. Though the sulphuric and organic acids present were not determined, the amounts of such acids contained in plasma are known to be very small, and would account for a small part only of the excess of base present. Secondly, about two-thirds of the total basic radicles are in combination with a strong acid, hydrochloric, as chlorides, while less than a quarter is combined with carbonic acid as bicarbonate. Only a small part, therefore, of the total base present goes to form the so-called "alkaline reserve" of the plasma, though it must be recognised that part of the base combined with hydrochloric acid is, in whole blood, available for neutralisation of added acid; for, with an increase in the amount of acid radicles present in the plasma, a shift of HCl occurs from plasma to corpuscles, leaving base available for bicarbonate formation.

TABLE I.—*Normal Cases.*

No.	Serum.			Plasma.		
	Na.	K.	Ca.	Cl.	P.	CO_2.
1	332	19·3	9·9	645	2·9	67·5
2	331	20·6	9·9	624	2·9	63·3
3	371	20·2	10·0	630	3·3	61·4
4	343	23·7	9·7	620	3·1	68·0

Diabetic Cases.

The most striking feature of the analyses in the diabetic patients (Table II.) is the absence of any appreciable reduction in the total bases of the serum, even in cases in which a very marked ketosis was present, and in which the alkaline reserve of the plasma showed a definite fall. In Cases 3 and 8, for example, the sodium and other bases of the plasma are at a normal level, though the bicarbonate content is reduced to about two-thirds of the normal figure. Though the reduction of the alkaline reserve of the plasma (plasma bicarbonate) suggests the picture of a general fall in the content of the plasma in basic radicles, such a depleted base content does not appear to be actually present. Similar findings are reported by Gamble, Ross and Tisdall[7] in a study of the acid-base metabolism during the ketosis produced by fasting, and of its effect upon the fixed bases of the blood. As is well known, large quantities of β-oxybutyric and di-acetic acid are formed in the body during a fast. Though a considerable fraction of the excess acid is excreted by the kidneys as free acid, and though a large proportion of the remainder leaves the body in combination with ammonia, a certain amount of fixed base is inevitably lost. In spite of this loss, the bases of the plasma were found to remain at an almost fixed level during the fast, though the plasma bicarbonate showed a definite reduction. Since there is no evidence of any increase in the inorganic acid radicles of the plasma to compensate for the diminution in HCO_3, the presumption is that the diminution of base normally bound as bicarbonate is compensated by an increase in base in combination with the ketone acids. Base which was previously present as bicarbonate is now circulating in combination with β-oxybutyric and di-acetic acids. The base content of the plasma tends to remain at a constant figure, though it is redistributed among the various acid radicles available, including the abnormal amounts of organic acids which are known to accumulate in the blood in these conditions. When we call to mind the manner in which other constituents of the blood tend to remain at a relatively constant figure under the varying environmental conditions to which the organism is exposed, this comparative fixity in the base composition of the plasma becomes less surprising. The loss of base in the urine is mainly met by drafts upon the tissues (Kingo Goto has, for instance, shown that, with long-continued experimental introduction of acids, the bones lose appreciable amounts of calcium carbonate); the bases of the plasma remain comparatively intact.

K = ketosis.

There are, in addition, indications of certain minor adjustments in the diabetic. (1) The inorganic phosphate content of the plasma shows, in some instances, a definite reduction. Such a reduction in the plasma phosphate might indeed be anticipated in diabetic acidosis; since the excretion of monobasic phosphate by the kidney liberates base for combination with the excess of organic acids present, the phosphate of the blood being mainly present in the dibasic form. (2) The plasma chlorides tend apparently to lie at a lower level than in the normal; this diminution in the chlorides is presumably the result of a shift of HCl from plasma to corpuscles, basic radicles being liberated for combination with the excess of ketone acids.

The blood picture suggests, therefore, that in diabetic ketosis the base content of the plasma remains relatively constant. An extensive redistribution of base occurs, however, between the acid radicles; the bicarbonate of the plasma undergoes a great reduction, shared to a lesser extent by the phosphates and chlorides, the base thus liberated entering into combination with the excess of organic acids which are present in the circulation in this condition.

Advanced Nephritis.

Advanced nephritis of the azotæmic type is the disease par excellence in which marked alterations in the inorganic constituents of the blood occur. The primary factor underlying these changes is the inability of the kidney to excrete phosphoric acid with resulting accumulation of the acid radicle in the blood. In addition, it has recently been shown by Denis that very marked accumulations of sulphates in the blood may result from this type of renal defect. We have, therefore, in this disease, as in diabetes, a tendency to an excess of acid bodies in the organism, due, however, in nephritis, to failure to excrete a normal quantum of acids rather than to any excessive acid formation in the body.

The well-known alterations in the inorganic blood picture of the nephritic in the terminal stages of the disease are (1) a great increase in the phosphoric (and sulphuric) acid radicles, and (2) since acids circulating in the blood are of necessity neutralised, abstraction of base from the plasma bicarbonate for combination with the acid excess, the volatile carbonic acid resulting being excreted by the lungs. The phosphate accumulation and the resulting bicarbonate deficit are obvious in certain of the cases included in Table III. (2, 8, 9, 10). In addition, the table shows the low calcium content of the serum which is peculiar to idiopathic tetany and nephritis, and which in the latter condition appears to be connected with the degree of phosphate accumulation (2, 7, 9).

TABLE III.—*Nephritis.*

U = Uræmia. Int. obs. = Intestinal obstruction.
Rec. = Recovered.

The potassium content of the serum in these cases gives no support to the old theory that uræmia resulted from an intoxication with potassium salts. In one case only (10) is a definite increase in the serum potassium present. As has already been pointed out, errors may arise in the potassium estimation owing to the passage of potassium from the red cells to the serum. Though in this case, as in all others, the serum was removed from the clot within two hours of withdrawal of the blood, it is possible that under pathological conditions alterations in the permeability of the corpuscles may occur, and lead to a more rapid diffusion of potassium into the serum. In one case (3) the potassium content of the serum was on two occasions found to be at a low level.

The variations in the plasma bicarbonate are of considerable interest. Though the diminution in the bicarbonate of the plasma is reasonably ascribed to the accumulation of phosphoric acid in the blood, it has been pointed out by Denis and Minot[5] that the phosphate increase and the bicarbonate decrease are not in all cases proportional. This cannot, of course, be ascribed to any sparing of the base in combination with the bicarbonate, by accumulation of ammonia in the blood. All the available evidence is in favour of the view that no such excess of ammonia is to be found in the blood of nephritic patients, and since the main basic radicles apparently remain at a fairly constant figure, some form of redistribution of base must occur, in which acid radicles, other than the bicarbonate and phosphate, play a part. The redistribution actually found is well illustrated by Case 3.

In the second observation on this case (20/8/23) it will be noted that while the phosphate and the various basic radicles remain comparatively constant, the bicarbonate and chloride vary inversely. A rise in the bicarbonate content is accompanied by a fall in the chlorides. Though this might be interpreted as the result of a shift of HCl to the corpuscles, the explanation is probably more simple. The blood examined on 20/8/23 was withdrawn at the end of a period of continuous uræmic vomiting. It is already known that in the vomiting of intestinal obstruction an extreme fall in the chloride content of the blood occurs, and that at the same time the plasmic bicarbonate rises to a figure much above the upper limit of the normal. The mechanism of these changes is probably as follows. Large quantities of HCl are lost in the vomit; this HCl is derived in the process of gastric secretion from the NaCl of the plasma, the residual Na combining with carbonic acid in the blood to form bicarbonate. Under normal conditions, the excess bicarbonate thus formed passes into the intestines with the pancreatic and intestinal secretions, and combines with the gastric HCl to form NaCl, which can be re-absorbed. With vomiting the circle is broken and, while the chloride content of the blood falls, the bicarbonate rises. The condition is illustrated in Case 6, in which obstruction of the ileum was present. Here, early in the course of obstruction, the chloride is noticeably low and the bicarbonate somewhat above the normal level; the urea retention present in this patient is a constant feature of the severer types of obstruction, and is apparently the result of definite renal damage. In Case 3 vomiting ceased shortly after the second blood sample was examined, and at the time of the third observation (17/9/23) a more normal distribution of the acid radicles of the plasma was present. The bicarbonate was now reduced in proportion to the phosphate accumulation, and the plasma chlorides had returned to a normal level. The cessation of vomiting was accompanied by an extremely rapid gain in weight, which may have represented the restoration of the chloride and water content of the body to a normal figure, since the water content is largely determined by the amount of chlorides present in the organism.

Cases 7 and 9 are introduced as illustrations of the low plasma chloride that may be found in cases of nephritis in which excessive vomiting has occurred. In both the chlorides were determined by the more accurate method devised by Austin and Van Slyke.[6] Case 7 presents an interesting contrast to Case 2. In both patients approximately the same degree of phosphate retention was present. Case 2, in which practically no vomiting had occurred, shows extreme bicarbonate reduction with a slightly high plasma chloride, while in Case 7 the bicarbonate content is relatively little, the chloride greatly, reduced.

It would appear, then, that the vomiting of uræmia may be regarded as constituting a protective mechanism. By removal of HCl base is provided and the bicarbonate content is to some extent conserved in spite of phosphate retention. The vomiting is not the result of the reduction of the bicarbonate, since vomiting is by no means a marked feature of diabetic acidosis.

Eclampsia and Pre-Eclampsia.

The findings in the pre-eclamptic state and in eclampsia (Table IV.) are of little interest. Apart from the increased chloride content of the plasma and the slightly diminished plasma bicarbonate, the concentration of acid and basic radicles examined approximates closely to the normal. The high chloride content is presumably the consequence of the impaired chloride excretion which is known to occur in this disease. The reduction of the plasma bicarbonate is, with the exception of Case 5, hardly greater than that found in normal pregnancies. In Case 5, three severe fits had just occurred when the blood was withdrawn for analysis, and the patient eventually died as the result of a series of convulsions. A gross depletion of the alkaline reserve of the plasma was present, and was not apparently the result of a ketosis, since traces only of acetone and di-acetic acid were present in the urine. It is possible that the diminution in the plasma bicarbonate was the result of extreme muscular exertion incident to the convulsions.

SOME OBSERVATIONS ON THE SCHICK TEST.

BY CLAUDE B. KER, M.D., F.R.C.P. EDIN.,
MEDICAL SUPERINTENDENT, EDINBURGH CITY HOSPITAL;

AND

JOHN McGARRITY, M.B., D.P.H. EDIN.,
SENIOR RESIDENT MEDICAL OFFICER TO THE HOSPITAL.

DURING the last 18 months we have been able to subject to the Schick test a large number of the patients admitted to the Edinburgh City Hospital, all the nurses, and most of the students attending the clinics. Our results, therefore, give some indication of the susceptibility to diphtheria of different groups of individuals, normal or suffering from one or other of the infectious diseases, and drawn from different classes of the population. It is to be regretted that the numbers of measles and whooping-cough patients are so small, but very few who were admitted escaped the test. The great majority of our scarlet fever patients were also tested. As regards the other infectious diseases only a few tests were made, the time at our disposal being limited.

Technique.—The toxin used was prepared by Dr. R. A. O'Brien and supplied from the laboratories of Messrs. Burroughs and Wellcome. The dose given was in all cases 1/50 of the minimum lethal dose for the guinea-pig, injected in 0·2 c.cm. of normal saline. This toxin gave very consistent results.

Reaction.—It seems unnecessary to describe the reaction. Those not familiar with it will find full descriptions in the papers of H. Mason Leete,[1] A. T. Glenny, K. Allen, and R. A. O'Brien,[2] and Gladys Ward.[3] Every test was controlled, the left arm being used for the injection of active toxin and the right for the inactivated toxin of the control. We worked together, one being responsible for the test and one for the control, a precaution which avoids the not unlikely errors of giving the injection into the wrong arm or of confusing the bottles containing the dilutions. As, with the exception of the student group, all our patients were in the same institution, we were able to watch the reactions closely, and every arm was examined on each of the first three days after injection and again on the tenth day. This we found very helpful in the study of pseudo- and combined reactions. The notes made on each examination have also been of use in determining the most suitable day for deciding whether a test is positive or negative, if, as must often be the case, only one examination can be arranged for.

It may be well to emphasise the fact that the test causes no discomfort to the patient, nor did one of the 4352 injections (tests and controls) raise any suggestion of septic inflammation. A few of the more intense reactions, certainly less than half-a-dozen, showed slight vesiculation. The only precautions taken were the scrubbing of the arms with ether at the site of injection and the dipping of the needles in alcohol between each test.

This table includes all individuals tested, patients suffering from scarlet fever, measles, whooping-cough, surgical tuberculosis, erysipelas, chicken-pox, puerperal fever, meningitis, &c.; all the hospital nurses, maids of the domestic staff, students, resident medical officers, and children of the staff.

Table I. gives the results of all the 2176 tests made, and gives some indication how susceptibility varies with age. It is generally held that immunity is gradually acquired by exposure to small and repeated doses of the diphtheria virus, doses which are insufficient to produce the actual disease. For the first few months of life the infant is protected by natural antitoxin transmitted from the mother, but this immunity, well demonstrated by our figures, is seen to decline rapidly, and between the ages of 1 and 3 years susceptibility is at its highest. After the third year immunity gradually increases, and this improvement is maintained in our cases up to the fifteenth year. If we had to deal with the city population alone the decline would doubtless continue, but the next age-period includes an increasing number of persons from the country, children for instance sent in to boarding schools, domestic servants, and after the age of 18 years a solid block of our own nurses, many of whom are brought up in country districts where presumably the chances of exposure to subinfecting doses of diphtheritic infection are much less than in town. It is the nurses also, now supplemented by a large group of students, who help to account for the singularly high susceptibility-rate between the ages of 20 and 25. Thereafter, though the numbers are too small to be taken seriously, the natural decline reasserts itself.

Table II. shows the susceptibility-rates of our scarlet fever, measles, and whooping-cough patients, and interesting differences between the diseases may be observed. It will be noted that the total percentage of positive tests in scarlet fever is distinctly high. The figure, 62·1 per cent., is not very different from figures found in the same wards in 1920 and 1921 by Leete[1] and Ward,[3] 57·2 and 56·0 respectively. It is considerably higher, however, than the 45 per cent., reported by A. Zingher,[4] of 1200 scarlet fever patients in New York, or the 47·4 per cent. of T. E. Dickinson's[5] Manchester cases. Yet Zingher considers that his figure is a high one when compared with that of the normal children whom he has tested, and points out that it agrees with the undoubted clinical fact that scarlet fever patients are unduly susceptible to diphtheria. This susceptibility, he explains, may be due to the destruction of the natural antitoxin during an attack of scarlet fever. Poliomyelitis is said to have a similar effect. It will be seen in our table, however, that at the most susceptible age-periods, from six months to three years, measles gives an even higher positive rate than does scarlet fever.

So far as our own cases are concerned, we are inclined to explain the high susceptibility noticed in scarlet fever by the character of the population dealt with. Our scarlet fever patients are a fair sample of the whole population of Edinburgh, as it has been the custom to isolate at least 95 per cent. of all the cases in the city. On the other hand, only a small minority of the measles and whooping-cough cases are sent into hospital, and these usually come from the poorest homes in the city. The whooping-cough children, in particular, may be said to represent the slum population. Zingher[6] has shown that the children in the poorer class schools in New York have a much lower susceptibility-rate than those from the schools in better districts. As a result of overcrowding and bad hygiene at home the class from which our whooping-cough patients come begins very early to suffer exposure to diphtheria and, as a result, acquires immunity very rapidly. Our measles patients, though mainly of a very poor class, are a little more mixed, and obtain immunity somewhat more slowly, though much more rapidly than does the scarlet fever group, as will be seen by a study of the percentage of positive tests at each age-period.

Students, Nurses, and Staff.—Table III. gives our results for three groups of adults, nurses, students, and hospital domestic staff respectively. The close correspondence of the figures relating to the nurses and students in the same age-period, from 20 to 30 years, is very interesting. All, no doubt, have been brought up in reasonably good hygienic surroundings and many are from country districts. The susceptibility-rate at this age seems unduly high, 63 per cent., but it accords with that of 65 per cent. found by O'Brien[7] and his fellow-workers in a group of 160 medical students. The much lower rate shown by the hospital maids seems to imply that social conditions have more influence than age in determining the development of immunity. A considerable proportion of our domestic staff comes from mining villages in the vicinity of Edinburgh.

Surgical Tuberculosis.—We took the opportunity of testing 59 patients suffering from this condition and found that, although no fewer than 42 were under 15 years of age, the susceptibility-rate was as low as 37·2 per cent. This group included children of all classes, though no doubt the majority were from poor homes. Ward [3] found that the percentage susceptibility was considerably higher in acute than in chronic diseases, and these figures, though too few to be of real value, appear to support her contention.

The gradual increase in the percentage of pseudo-reactions as age advances is well shown in Table IV. It would appear to justify two deductions. In the first place, the number of pseudo-reactions in children of under 5 years of age is so very small that it would appear quite unnecessary in their case to trouble with a control test. This test, indeed, might well be omitted also in the succeeding five years of life, the risk of error being still very slight, and the worst that could happen being the unnecessary immunisation of three children in every hundred. The second deduction is that, with so little susceptibility to bacterial protein at these ages, troublesome reactions to the immunising injections are most unlikely to occur. That in fact they do not occur in young children is the experience of all who have had much to do with immunisation work. We were, therefore, able to advise the Edinburgh public health authorities that they could safely lessen the amount of work by dispensing with control tests, and that it was extremely unlikely that they would be troubled with severe reactions. In the schools which they have since protected they have found this to be the case. It is satisfactory to know that those who require immunisation most—i.e., the children—are so little upset in the process. As regards adults, unless, as is the case with nurses, their duties bring them into contact with diphtheria, there is not so much to be gained by inoculation and, if they present pseudo-reactions, it is a question whether immunisation is worth while, as it is in this class of persons that troublesome reactions are most likely to occur.

TABLE IV.—*Pseudo-Reactions: 2176 Tests.*

15–20	26·7	53·5			
20–30	31·4	59·3	Totals..	13·0	61·2

As all our cases were controlled there was no difficulty in recognising pseudo-reactions. The real trouble, however, was, if a pseudo-reaction was present, to determine whether the Schick test was positive or not. To make certain an opinion cannot be given for ten days, and in some of our cases it was necessary to wait even longer before coming to a final decision. Where a combined reaction is present it leaves much more definite pigmentation and desquamation than is to be seen on the control arm, and the diagnosis depends on the contrast between the reactions on the two arms at about the tenth day. We found in our nurses and students that combined reactions were by no means uncommon, and we have been able to satisfy ourselves that, after immunisation, this "positive and pseudo" reaction disappears, the next Schick test resulting in absolutely identical appearances on both arms and being classified as "negative and pseudo." We are therefore compelled to disagree with Dr. O'Brien's suggestion that cases presenting a pseudo-reaction are immune and therefore do not require toxin-antitoxin injections. As was to be expected, pseudo-reactions were much more common in persons already sensitised to bacterial protein. Of 170 individuals who gave a definite history of having been treated at some previous date with horse serum, either antidiphtheritic or antitetanic, 67, or 39·4 per cent., were pseudo-reactors as against only 13 per cent. of all persons tested.

The Test in Acute Diphtheria.

As a matter of interest we tested 55 diphtheria patients on admission and obtained a definite positive result in 54 of them. All tested had definite clinical and bacteriological diphtheria, and it was naturally expected that all would be positive. It is interesting to note that the subsequent course of the one negative case led to a suspicion that an error in diagnosis may have been made, and that in reality the case was one of septic infection occurring in a carrier.

The Test in Relation to Previous Attacks of Diphtheria.—Of 157 patients who gave a history of having suffered previously from diphtheria, 46·4 per cent. had positive reactions and were regarded as being susceptible to the disease.

Effect on Test of Recent Treatment with Antitoxin.

In the course of our work we subjected to the test 37 individuals who for various reasons had received prophylactic injections of antitoxin within three weeks prior to the test. These patients naturally are not included in our tables. All were negative except one who gave a definite positive reaction 12 days after a 500-unit dose. Clinically, our hospital records do not show an instance of any patient so protected developing diphtheria in less than 22 days after such a dose, though we understand laboratory work goes to show all antitoxin may have disappeared from the blood in 12 days. For all practical purposes we think a prophylactic injection may be trusted to give protection for three weeks.

Incidence of Diphtheria in Positive and Negative Cases.

During the time we have been engaged in this work 13 individuals, who had been tested, contracted diphtheria, some in hospital and some at a later date. Of these, 11 had given a definite positive reaction. In the two others the reaction had been noted as negative, but in one of them it was found that the test had been made within a fortnight of an antitoxin injection and was therefore of no significance. The remaining patient, one of our own nurses, had originally given a positive test, had then been immunised, and some months later re-tested. On this occasion a slight reaction was noted on both arms at 24 hours and nothing convincing thereafter. She was classed as negative and later took diphtheria. It is, of course, possible there may have been a very slight positive combined reaction, but it seems reasonable to regard this case as one in which the test definitely failed.

Delayed Reactions.

The possibility of delayed reactions is of some importance, especially if only one reading of the test can be arranged and if that reading is made too early. The suggestion has been made that 95 per cent. of readings made at 24 hours are proved to be accurate. We consider this percentage, as judged by our own experience, far too high. We have often had to wait 48 hours for any real indication of the ultimate result. In feeble and badly nourished children, in particular, the reaction appears to come up slowly. It will be sufficient to give the figures relating to the whooping-cough patients. Of the 75 cases ultimately classed "positive," only 17 showed anything on the arm at 24 hours, by 48 hours 37 had become positive, by 72 hours 62, the remaining 13 reactions appearing in most cases at 96 hours, but in one or two even later. It may be admitted that this group consisted of very young and feeble children, many of whom were suffering from broncho-pneumonia. The figures, however, show that definite conclusions cannot be drawn even from 72-hour readings.

Anomalous Reactions.

With one particular batch of inactivated toxin we obtained the somewhat disconcerting result of a reaction on the control arm only. We were able to satisfy ourselves that this anomaly was not due to any mistake in the inoculations or to using the wrong bottle for the test. In all 13 reactions occurred on the control arm alone and in 18 more the control arm showed a much more marked reaction than the others. Béguet and Parrot [8] have described similar reactions which they term "paradoxal." In 100 children they observed 21 such results, chiefly in children of over 10 years of age. They conclude that the heating of bacterial proteins causes a definite increase of their toxicity for certain subjects. This hardly explains the rarity of this curious reaction or the fact that, in our experience, it was only observed in one group of individuals who had been tested with the same batch of inactivated toxin. In any case, a phenomenon which has so seldom been reported may be regarded as of little consequence.

Conclusions.

From the study of our results we have come to the conclusion that the Schick test might be omitted so far as children of under school age are concerned. Such a high proportion of these give positive reactions that it would be reasonable to proceed with immunisation at once. In older children, up to the age of 10 years, it seems unnecessary to make use of the control test. It is highly desirable to simplify the procedure in every way so that as few injections as possible have to be made. If it is possible to arrange for two readings of the reaction these are best made on the fourth and tenth days. If one reading only is practicable the eighth day appears suitable, and the first immunising dose can be given at the same visit.

We have not in this paper touched the question of immunisation which is, of course, the logical sequence of the Schick test. The immunisation, however, of all the hospital nurses, who proved Schick "positive," has been carried out by one of us and the results so far have been promising. We require more time for the study of the after-history of the protected persons, but it is hoped that a preliminary note on the effect of the toxin-antitoxin inoculations will soon be ready for publication.

TREATMENT OF SYMPTOMS IN INOPERABLE CANCER WITH LIQUOR POTASSÆ.

BY DOROTHEA M. GALL, M.B., CH.B. EDIN.,

HOUSE SURGEON, YORK DISPENSARY.

I SHOULD like to bring to the notice of my colleagues some cases of inoperable malignant disease which I have been treating for some months with liquor potassæ.

CASE 1.—Mrs. B., aged 40, has had a history of gastric disturbance over a period of 12 years. Four years ago she noticed a "lump" in her left side below the rib margin. This gradually enlarged and she began to have attacks of pain and vomiting, which became more severe until December, 1922, when she was sent into hospital for operation. After admission she had a severe hæmatemesis. At operation an inoperable cancer of the pylorus was found, and a gastro-enterostomy was performed as the pyloric opening was almost closed. She was discharged in February, 1923. During the year the symptoms continued, and the pain was so severe as to interfere with sleep. There was increasing weakness and cachexia. On Sept. 10th, 1923, I found the patient in great distress, crying out with pain and with almost continual vomiting. She was very emaciated and her complexion was greyish-yellow. The abdomen was rigid, and there was a hard, irregular mass about 2½ inches in diameter in the left hypochondrium. Above and median to the mass some small separate nodules were palpable. There was marked tenderness and dullness in the epigastrium, and also over the mass. I gave morphine four-hourly for three days without much relief. On the third day I found her delirious with pain and exhaustion, and prescribed the following: ℞ Liq. potassæ, ♏xv.; pot. nit., gr. x.; aq. menth. pip., ad ℥ss.; ʒss., t.i.d., ex aq. a.c. The result of the first dose was dramatic. The patient slept many hours without waking, and next day the pain was very much relieved and there was no vomiting.

I have continued with this treatment for the past four months with the following results. The pain has gradually lessened in severity and frequency, until now it is negligible. There has been no vomiting whatever since Sept. 13th. The small nodules disappeared within a fortnight, and the large mass is now reduced in size by more than half. In the morning, when the stomach is empty, it is not palpable at all. The patient's general condition has steadily improved. She has gained in weight week by week. Her complexion has become normal. She is able to walk three miles without any discomfort. Her appetite is good, and she can eat almost any food without pain. After the first month I increased the dose of liq. potassæ to ♏xx. and later to ♏xxv. On Dec. 10th I reduced the dose to ♏xv. For the past few weeks the gain in weight has been maintained with administration of the medicine every alternate week only. The patient assures me that any pain she has had since September has been due entirely to flatulence.

CASE 2.—Mrs. C., aged 36, had a radical operation for cancer of the breast in January, 1923. When I saw her on Nov. 20th she complained of "rheumatism" in the back, in the interscapular region, and in the shoulders and right arm. She also complained of a lump in her neck. On examination I found a hard, immovable mass in the lower part of the posterior triangle of the neck. The upper border extended about 1½ inches above the clavicle, and the lower border could not be palpated beneath the clavicle. Immediately above the mass were some hard nodules—defined and movable. The right shoulder was raised and the head held slightly towards that side. She looked ill, and her complexion was very sallow.

She was treated with potassium by mouth for one month, and during that time her general condition improved enormously. Her appetite improved at once, she grew much stronger, was able to get about out of doors, and her skin lost its sallow tinge. In three weeks the movable glands had disappeared, but I found it very difficult to determine whether the mass extending beneath the clavicle had reduced in size. The pain was not much relieved.

CASE 3.—Mrs. W., aged 69, had a history of pain and vomiting after meals, and also of frequent acute attacks of pain and vomiting without relation to food for some years. In the summer of 1921 operation was advised, but she refused to go to hospital. When I saw the patient on Nov. 29th, 1923, she was exceedingly emaciated and of a deep yellow colour. She was too weak to raise herself in bed, did not recognise the members of her family, and was alternately comatose and delirious. Her pulse was weak and irregular. There was a subnormal temperature, vomiting was frequent and severe—"coffee-ground." She had not slept for five days and nights. On examination the emaciation was extreme. The abdomen looked "lumpy," and the skin over it wrinkled and deeply pigmented. On palpation there was marked resistance and tenderness in the epigastrium, and an irregular, hard, nodular thickening over the abdomen. There was no free fluid. There was no mass palpable in the left hypochondrium, but extensive dullness on percussion. Liquor potassæ was given, and after the first dose the patient slept 14 hours, and awoke without pain or sickness and mentally clear. During the next three days she had two attacks of vomiting, but they were not so severe, and after six doses they ceased altogether. Her pulse grew stronger daily, and she had very little pain. At the end of a fortnight she was able to sit up in bed unsupported, was hungry, and having good nights. A month later the epigastric tenderness had disappeared. There had been no vomiting whatever. The complexion was almost clear, and the skin of the face less wrinkled. On Dec. 28th following she had an acute attack of pain and some vomiting, which was quickly relieved with morphine.

Although none of these cases is cured, they have all shown such remarkable improvement under the administration of potassium in this form that I think further investigation and wider application of the treatment than my own work permits is merited. The results generally, and the almost startling relief after the first dose of liquor potassæ, have led me to consider whether there may not be some specific effect of potassium upon cancer growths. It has been shown that "the potassium content of the red corpuscles of cancerous patients is approximately double that of healthy persons," and "chemical analysis of 300 tumours showed preponderance of potash salts and nucleo-protein content, associated with high virulence and rapid development."

The question arises whether potassium be a natural agent used by the body to control the perverted metabolism of tumour cells.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF EPIDEMIOLOGY AND STATE MEDICINE.

A MEETING of this section was held on May 23rd, Dr. MAJOR GREENWOOD being in the chair.

A resolution was carried expressing the profound grief of the section occasioned by the death of Dr. Richard J. Reece, their President, and their deep sympathy with Dr. Reece's family and colleagues. On the recommendation of the Council of the section it was resolved to hold the ordinary meetings of the section in the session 1924–25 at 5.30 P.M. on the fourth Thursdays of the month.

The Elucidation of Cancer.

Dr. LOUIS W. SAMBON read a paper on this subject. He gave an account, illustrated by numerous lantern slides of classical sculptures, of the knowledge possessed by the ancient civilised races of malignant disease, and then indicated the analogies between cancer and certain diseases, such as elephantiasis, of parasitic origin. He described the field investigations he had recently carried out in parts of the province of Romagna (corresponding roughly with the eastern part of the departments of Emilia and Tuscany, in the neighbourhood of Forli and Fiesole) which led him to conclude that cancer was a parasitic disease, possibly caused by a nematode of which the cockroach was an intermediate host or carrier. Dr. Sambon dwelt on the importance of Fibiger's researches on the gastric carcinoma of rats caused by eating infected cockroaches, and entered a strong plea for the extension of field investigations such as that he had just completed. In his opinion, it was by such field work rather than by the comparison of statistics that the ætiology of cancer would be elucidated.

The CHAIRMAN said that the very remarkable differences in rate of mortality from certain forms of cancer which distinguished England and Wales, Italy and Holland, were at present the object of an international inquiry, and the national representatives would certainly take note of Dr. Sambon's results.

Dr. R. DUDFIELD said that Dr. Sambon had given reasons for a reconsideration of the question of "Cancer Houses," and he (Dr. Dudfield) intended to pay special attention to this point.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

A MEETING of this Association was held at the Elizabeth Garrett Anderson Hospital on May 13th, Miss M. CHADBURN presiding.

Bacteriophage.

Dr. E. LEPPER read a paper on Bacteriophage, with lantern illustrations. She showed cultures demonstrating the chief characteristics of a bacteriophage—namely, (1) inhibition of bacteriological growth, (2) lysis of bacilli, (3) filtrability, (4) resistance to heat, (5) reproduction when incubated with a sensitive, growing organism, (6) the production of bacteriological variation. The bacteriophage used in her experiments was isolated from the urine of a woman suffering with bilateral pyelitis due to *B. coli*. It is lytic for the organisms grown from the urine of the same patient, and from some other strains of *B. coli* as well. She showed lantern slides illustrating the marked immediate effect of a strong bacteriophage on a sensitive culture. She found that a dilution of 1 in 100 bacteriophage reduced the number of colon bacilli present in an emulsion from 2500 per drop to 10 per drop in 15 minutes; a dilution of 1 in 10 of the same bacteriophage took 1·5 minutes to produce the same result. She suggested that such a bacteriophage might be introduced into the pelvis of the kidney in cases of *B. coli* pyelitis when the causative organism was sensitive to its action.

Dr. IRIS FOX read a paper on the

Use of Vaccines and Sera.

She discussed the attitude to this subject of the medical profession, noting the acknowledged value of prophylactic vaccination in certain specific infections, and its apparent failure in certain other specific diseases, and concluded that the possibility of adequate protection against non-specific invasions was, on the whole, considered unproven. There was greater general confidence in the prophylactic rather than the therapeutic use of vaccines. Passive immunisation with specific serum was accepted as the unique curative or prophylactic measure in diphtheria or tetanus. Miss Fox expressed her own belief in the future of artificial immunisation. We had here a powerful—perhaps the most powerful—weapon against disease, but had not yet the knowledge to use it properly. For example, there was the widest variation in the doses given and the reactions arrived at. In the case of prophylactic inoculation against the enteric fevers the large initial dose was given of 500 million *Bacillus typhosus*, with 250 million each of *B. paratyphosus* A and B. An example of much higher initial dosage was the method of inoculation against pneumonia used in South Africa by Spencer Lister, who gave a first injection containing 6000 million each of four different pneumococcal strains. Every kind of vaccine had been, and still was being, given on a large dose system in which a slight or moderate constitutional reaction was desired, and, on the other hand, in comparatively minute doses, aiming at immunisation without the production of any general disturbance. There was, she thought, an increasing tendency to use small doses in treatment. There was just as much difference of opinion concerning the interval between injections and the importance of the negative phase. It was difficult to determine the relative value of different techniques in our ignorance of the immunising processes of the body. Laboratory attempts at exact measurement of immunity production had unfortunately been of no more help than had vague clinical impressions as to the value of this or that proceeding. Protection against, or cure of, disease in the animal body was not always proportionately indicated by a high serum content of demonstrable antibodies, such as agglutinins. It seemed likely that specific antibody content was not the only factor in immunity, and much work, and probably considerable alterations in our conception, was needed before specific therapy could be properly controlled. Miss Fox proceeded to discuss the question of specific and non-specific therapy and the collection of material for bacteriological diagnosis. She dealt briefly with active immunisation against diphtheria, which had passed the experimental stage and was being practised with great success in America; also with the typing of pneumococci and with the beneficial results, in the Rockefeller series of cases, of the specific antiserum in Type 1 cases. She referred to the work of Miss Mary Cowan on the rough and smooth varieties of the hæmolytic streptococcus and to the possible clinical application of this work.

Dr. MARY COWAN said that from a single strain she had been able to isolate a rough and a smooth type of hæmolytic streptococcus, of which the smooth was virulent and the rough was not. She tried to immunise mice and rabbits, and in mice was able to give immunity by a serum produced from the rough to those infected with the smooth variety. In rabbits this was only possible in a very small percentage. When using a smooth strain alone she had 66 per cent. of successes. The serum of protected rabbits gave great variation in agglutinin content; some animals which had agglutinisation of a very low titre lived, and others with a high titre died. No relation was found between agglutinins and useful antibodies.

EDINBURGH OBSTETRICAL SOCIETY.

A meeting of this Society was held on May 14th, Prof. B. P. Watson, the President, being in the chair.

Pelvimetry.

Dr. S. J. Cameron and Dr. J. Hewitt (Glasgow) communicated a note on pelvimetry. Dr. Hewitt, who read the paper, pointed out the fallacies attending the performance of the bimanual examination as described and illustrated in the text-books. He considered the Munro Kerr manœuvre, in which the fingers of one hand, in a position of semi-supination, were introduced into the vagina, while those of the other attempted forcibly to depress the head into the brim—a physical impossibility. In cases of small pelvis associated with a pendulous abdomen, one hand alone could not press the head down, and, further, the thumb was not in the right position to estimate the degree of overlap at the pelvic brim. Ballantyne, in 1921, had recommended the help of an assistant in the performance of the bimanual examination in these circumstances. They therefore recommended that the fingers should be passed into the vagina with the hand and forearm in the position of full supination. The tips of the examining fingers then came into contact with the fœtal head, and not the lateral side of the fingers as in the illustrations in the text-books. If the head was now pressed down into the pelvis by an assistant the sensitive finger-tips were able to estimate the degree of descent, and after this had been done it was possible for the free and unrestricted hand to estimate the degree of overlap at the brim.—The President expressed complete agreement with the authors of the paper.

Dr. Haig Ferguson said that the fingers in the vagina also helped to indicate that the head was descending in the proper axis.

Dr. William Fordyce emphasised the importance of flexion and head moulding when attempts were made to estimate the relative proportion between the fœtal head and the pelvic brim.

Dr. Fraser Lee and Dr. R. W. Johnstone also took part in the discussion.

Dr. Cameron communicated a record of

One Hundred Successive and Successful Cases of Cæsarean Section.

He briefly described the technique which experience had led him to employ in the performance of this operation. Having seen cases return to hospital with large ventral hernia in which approach to the abdomen had been obtained by means of a mid-line incision, he had now abandoned this in favour of the approach through the rectus, with most satisfactory results. He preferred catgut to silk in the closure of the uterine wound on account of the fact that silk was not absorbed ; it gave rise to adhesions and he had seen a sinus, through which menstruation took place, due to the presence of unabsorbed silk in the uterine wall. It was well known that pathogenic organisms might lurk in the skin, however thoroughly it had been prepared before operation, and for this reason he set aside the knife with which the primary incision was made and covered the skin edges with gauze. He believed in leaving adhesions alone and often used the transverse fundal incision. 1 c.cm. of pituitrin was injected directly into the body of the uterus. After losing a number of cases from causes attributable to the anæsthetic, chloroform was now used as a routine. Cases complicated by bronchitis, catarrh, or emphysema stood the administration of ether badly, and chloroform in careful hands had given better results. Should signs of chest trouble be present these patients were placed in a steam tent immediately after operation, and the benefit they obtained from this line of treatment was often remarkable. All cases after operation were placed in the Fowler position.

Dr. Haig Ferguson, Dr. Fordyce, and Dr. James Young took part in the discussion.—Dr. Camreon, in reply to questions, pointed out that by a successful Cæsarean section he meant one which was successful from the maternal point of view. Fœtal deaths occurred now and then, as in general obstetrics. In his later cases he had perhaps been more careful in the selection of his patients.

Dr. E. Farquhar Murray (Newcastle-on-Tyne) read a paper on

Cæsarean Section.

His observations were based on an operative experience of over 100 cases, with special reference to clinical and pathological findings in cases of obstructive labour and describing a new operative technique in infected cases. This paper recorded an experience of 116 sections, the majority of which were performed to anticipate or relieve obstructed labour due to pelvic contraction, the others for less common indications. The operation, which takes from 12 to 20 minutes, was briefly described. The gaping mouths of sinuses seen while incising the uterus had suggested to the author that a safer method of approach must be adopted in septic or suspect cases. The placenta was found posterior or anterior in proportion of 4 to 3, but in cases where section had previously been performed the proportion was 3 to 1, suggesting that the residual scar-tissue contributed to this result. Rupture of an old scar was a negligible risk. It happened in one case on whom four previous sections had been performed. The complete ovum was found in the abdominal cavity, and the uterus, firmly contracted, was re-sutured, the mother making a good recovery. The previous obstetric histories of patients with contracted pelves were often instructive. One 7-para reported that her four children delivered alive with forceps died between 6 and 12 weeks from fits. Primiparæ having no antecedent obstetric history were entirely dependent for their safety on a pre-maternity examination. Contraction of the pelvic outlet he had found to be less common, but more treacherous than at the brim. Discussing the operative findings, Dr. Murray pointed out how Bandl's ring frequently corresponded with the position of the child's neck. The lower uterine segment was thin in cases of over-distension—sometimes no thicker than wet blotting-paper—and in two cases blood was extravasated under the peritoneal coat, indicating that it was on the point of rupture. The damage from trauma, to which the lower uterine segment, cervix, and vagina were subjected, and which results in obstructive labour from natural forces, was not sufficiently recognised. Referring to the placenta and membranes, it was noticeable that in a case obviously infected at a late stage the chorion appeared yellow and pultaceous in the lower areas and could not be stripped off, suggesting that infection was tracking up in this layer outside the amnion. The liquor in such a case was, as a rule, scanty and contained meconium ; in a number of cases it was definitely offensive. Many hours in labour, much interference, or the presence of Bandl's ring he looked upon as strong presumptive evidence of infection. A discharge developing during labour, after rupture of the membranes, was almost certain proof. Offensive liquor found on opening the uterine cavity, or a culture obtained from liquor per abdomen, was proof positive. Dr. Murray described his operative technique in infected cases in detail. His practice has been to have the patient placed in the lithotomy position and the vagina then douched out with eusol. The uterus is eventrated and held well forwards, and after being packed round with swabs, the edges of the abdominal incision are clipped together over the swabs. Towels are wrapped round the uterus outside the abdomen and are further protected by a layer of rubber sheeting. The fundus is incised transversely and the child extracted. An assistant holds the anterior and posterior walls apart, and thus prevents separation of the placenta until the muscular funnel lined by the placenta and membranes has been well douched out with eusol, the fluid escaping readily at the vagina. The placenta and membranes are then pressed down into the vagina with swab pressure, and extracted from below. The cavity is flushed again with eusol and the uterus and abdomen closed. The peritoneal cavity is well protected, and the uterine incision avoids the very vascular placental site, which is protected from infection until the membranes have been well flushed. Extraction of the placenta from below prevents the more highly infected membranes in the lower pole from being dragged over the placental site and wound edges. This is only possible if the os is half or more dilated. This technique has been adopted in five cases, but in one the placenta had to be extracted through the abdominal incision owing to insufficient dilatation of the os. One very late case died. All the cases were believed to be infected, although proved by cultures in two only, both of whom survived. Four live children resulted, the fifth being dead at the time of operation. Dr. Murray then proceeded to describe his results of Cæsarean section for various conditions such as placenta prævia, occipito-posterior cases, and tumours complicating delivery. The question of accessibility and vascularity would decide whether to attempt the removal of fibroids at the time of section or to postpone till involution was complete. In infected cases the latter course was certainly the wiser one to adopt.

Prof. WATSON said that he was much impressed by the details he had heard from Dr. Murray of his technique in septic cases, and wished to congratulate him on the way in which he had tackled this difficult problem.

Dr. JOHNSTONE said that he would be anxious to use Dr. Murray's methods when next he had the opportunity.

Dr. FORDYCE was interested particularly in the removal of the placenta and membranes from below, and questioned the efficacy of the intra-uterine douche. In one case quoted by Dr. Murray at the post-mortem examination organisms had been found in the uterine musculature and here douching would have been ineffective.

Dr. YOUNG, Dr. FERGUSON, and Dr. HUGH S. DAVIDSON also spoke.

Exhibition of Specimens.

Dr. W. T. THEODORE HAULTAIN showed an unusual broad ligament cyst with a twisted pedicle. A specimen of a double uterus, which had given rise to dysmenorrhœa, was demonstrated by Dr. MURRAY.—Dr. CAMERON showed two cases of chorion epithelioma, one showing scattered areas of growth in the uterine wall and in the other the tumour was found in the cervix, the symptoms and signs being suggestive of a rapidly advancing cervical carcinoma.—Dr. FERGUSON showed two specimens of ovarian cyst with twisted pedicle and hæmatosalpinx.—Miss G. HERZFELD showed a large mass of fibroids which filled more than half the abdomen. The upper pole of the tumour was hidden behind the left costal margin and the difficulties encountered at operation were briefly described. She showed also a photograph of a minute adenomyoma of the uterine wall. In the course of an operation a puckering and roughening of a small area of peritoneum on the posterior surface of the uterus was noted, and on removing a portion and subjecting it to microscopic examination the tissue revealed itself to be an adenomyoma.

CARDIFF MEDICAL SOCIETY.

A MEETING of this Society was held on May 13th, with Mr. WILLIAM MARTIN, the President, in the chair.

Dr. HERBERT EVANS read a paper on

Heart-Block.

Beginning with a definition which included all varieties of intracardiac type, he proceeded to give a description of the anatomical points involved and of experiments carried out on the hearts of the frog and tortoise, whereby several kinds of block had been produced. This was followed by a classification into types according to the anatomical lesion or grades from the clinical standpoint. These were illustrated by a series of lantern-slides and electrocardiograms, and their usefulness in giving the exact location of any interference in the conduction system was demonstrated. In discussing the ætiology a large number of cases were referred to, and the predominance of males over females was noted. The majority of cases occurred in men over 45. Of the causative conditions chronic myocarditis was the commonest, then came chronic valvular lesions (mitral stenosis), chiefly rheumatic, arterio-sclerosis, syphilis, acute infections, and over-administration of digitalis. Stress was laid on the fact that heart-block was but rarely a separate entity and should be regarded as a part of other cardiac involvement. There were very few symptoms associated with heart-block, and these only occurred in the high grades; they were due to the slow ventricular rate which, when below 20 beats per minute, caused cerebral anæmia, a suspension of the mental functions, and a possibility of fits. This constituted the Stokes-Adams syndrome, which, however, was not synonymous with heart-block since the majority of cases never had fits. In addition the general nutrition suffered and the mental aspect became affected. The symptoms usually met with were those of the associated cardiac lesion, which should be sought for in all cases.

The diagnosis of complete block was generally straightforward. That or the other types was best arrived at by means of special instrumental methods, although there were often suggestive signs —e.g., a pulse-rate below 50, dropped beats, which had to be distinguished from premature contractions. A sudden drop in pulse-rate during the course of or during convalescence from acute infections was always suggestive. In auricular flutter, a condition in which block frequently existed, the pulse-rate was often rapid. From the prognostic point of view, heart-block per se did not kill. The general condition of the cardiac muscle had to be taken into account. It was only a sign that the conducting system had become involved. High-grade block with serious cardiac lesions rendered the prognosis grave. Danger was likely to arise during the change from a partial block to complete block, and also during the state of "status epilepticus," or when arising during convalescence from an exhausting illness. Cases of block were known to live for many years. The greater number of cases died from general cardiac failure, with its accompanying signs. Treatment was for the most part singularly ineffective. Cases in which syphilis was the possible cause were likely to receive great benefit from suitable treatment. During attacks of block rest in bed was essential. Chronic cases were often able to carry on, but usually their power was limited. In the mild cases digitalis could be safely given, although the degree of block was increased. No treatment for the fits had yet been found. Atropine had been suggested. Patients should be warned of the possible dangers that might arise from these fits.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

JOINT MEETING OF THE SECTIONS OF MEDICINE AND SURGERY.

THE DIAGNOSIS AND TREATMENT OF INTRATHORACIC SUPPURATIVE CONDITIONS.

A JOINT meeting of the Sections of Medicine and Surgery was held in the Royal College of Physicians of Ireland on May 9th. The President of the Medical Section, Dr. T. GILLMAN MOORHEAD, was in the chair.

The PRESIDENT, in opening the discussion, referred to the difficulty in diagnosis of post-pneumonic empyema arising from the fact that the physical signs so often differed from those which were usually accepted as characteristic of fluid in the chest. In many cases loud tubular breathing, and even crepitus, could be heard over encysted collections of pus. In every case of doubt exploratory puncture should be performed. This procedure he regarded as absolutely free of risk, in spite of the alarming and dramatic reports of sudden collapse due to pleural shock which were from time to time recorded. Most of the text-books insisted that anæsthesia was dangerous, and as a matter of fact it was very seldom required, but in dealing with young children he had often found that general anæsthesia was necessary, and he had never experienced the least distress or harm to the patient as a result. He expressed the opinion that, except in cases of very small empyema, surgical treatment was always essential. In the past he had tried again and again to cure cases by repeated aspiration, coupled with vaccine-therapy, but never with good results, and in consequence he was an absolute disbeliever in this method of treatment. In acute cases following pneumonia aspiration might be required to tide over the acute period, but as soon as possible an opening operation should be performed. He then referred to some cases of acute chest arising from the rupture of small pleural abscesses into the general pleural cavity, a condition with which one had become familiar during the influenza epidemic, and which had proved the cause of sudden death in many cases during the course of that epidemic. In conclusion he dealt with the diagnosis and treatment of pulmonary abscesses.

Sir W. DE COURCY WHEELER said that he would not touch on the ætiology or the bacteriology, although surgical treatment depended largely on the particular organism found in empyema. He attached some importance to the maintenance of a negative pressure and airtight drainage in cases of empyema. In young children he employed the method recommended by Poynton and Reynolds with his own modification of the trocar and cannula. The trocar and cannula were plunged into the chest between two ribs, and a rubber tube of larger diameter than the cannula, with a lateral eye, but tied at the end, was stretched on a ramrod and introduced through the cannula into the chest. The cannula was fixed to the chest by means of a flange tied with tapes round the chest. The tube was connected with a two-bottle drip-pump, producing a negative pressure of about 8 mm. of mercury. There was no change of dressing until the cannula was finally removed in about a week. In cases where rib resection was necessary airtight suction drainage could also be obtained by passing a rubber tube through a finger-stall with large rubber flange from which the top had been cut off, mastisol being used for sticking. Chronic cases could be treated by (1) Carrel-Dakin method, (2) decortication of the lung, (3) Estlander's operation. In conclusion he discussed the treatment of pulmonary abscess.

Sir JOHN MOORE agreed with the President regarding the frequency of empyema in cases of diplococcic pneumonia infections, especially in children. These cases, if taken in time, generally did extremely well. He always had found the greatest difficulty in differentiating between empyema and hypophrenic abscess.

Mr. R. A. STONEY said that during the late war he was stationed near a depôt where there was a bad epidemic of pneumonia among African soldiers. A great number of the cases had ended fatally, and most of those who did not, developed empyema. He then saw the condition which had been described by old writers as "empyema of necessity," because in a great many of the cases the empyema had been present for so long that it had burst itself, and was discharging through the chest wall. He had found hypochlorite solutions very useful in these cases. He also found that empyema could be cured without obliterating the cavity of the pleura. He washed these cases out daily, and the discharge was reduced pretty rapidly, but in one case the tube came out during dressing, and owing to difficulty in getting it back he had left it out. The patient's temperature did not rise, and there was no further discharge of pus from the cavity. He concluded that the cavity had become sufficiently sterilised to allow the curative power of the pleura and its secretions to destroy any infection left behind. He agreed that vigorous and early operation should be undertaken. He personally removed a piece of rib in every case, whether child or adult, generally a piece of the eighth or ninth rib in the back. He washed out the pleural cavity thoroughly and put in a double tube, making a tight closure of the wound round the tube. He gave the patient respiratory exercises as early as it was possible to do so.

Sir WILLIAM TAYLOR said that free needling of the chest was certainly a help in the diagnosis of cases of empyema. He had only once experienced any ill-effect after needling, and that was in a case when almost directly after the needle had been put in the patient brought up blood and nearly suffocated. Morphia was given and the patient recovered. He never hesitated to needle a case several times, and he put in the needle inches deep. He thought the bacteriological standpoint was an important one in connexion with the surgical treatment of empyema. If the case was tuberculous, it was best left alone. If the infection was found to be purely pneumococcal, he believed in opening the chest very widely and freely, removing every particle of fibrin round the chest, sponging it out with disinfectant, and then sewing it up. He generally aspirated the patient within 24 hours, and again within 48 hours if necessary, and allowed the patient up within five days.

Dr. V. M. SYNGE said that he thought that in cases of small localised empyema a sign of some importance was the presence of ægophony. In cases of encysted empyemata X rays were very helpful in localising the pus. Sometimes when no pus was discovered the needle was found to be blocked by a piece of skin. It was well to have ½ c.cm. or 1 c.cm. of sterilised water in the syringe before inserting the needle, as this cleared the lumen and avoided getting skin on the needle. Empyemata in children were, he thought, frequently primary, as the condition was often found in cases where there was no history of pneumonia. It was said that streptococcal empyema was more serious than pneumococcal empyema, but he personally thought there was not much difference, as cases of one got well as quickly as cases of the other.

Mr. W. PEARSON said that a surgeon should satisfy himself as to the details of diagnosis, and not merely be content with the diagnosis given to him by the physician. Encysted empyema should be felt for when less pus was found than was expected. There was not much to choose between the scapular line for drainage and the axillary region, but he preferred the latter as it caused less discomfort to the patient.

Mr. HENRY STOKES had not found X rays of the least help in diagnosis of these cases. He did not think it was necessary to resect ribs.

Dr. T. G. HARDMAN said that he found X rays one of the most important methods of diagnosis. At private houses, of course, it was only possible to take photographs, but screening was even more useful. It was not possible, of course, to differentiate by means of X rays between a serous effusion or a purulent one, and for this one had to rely upon the clinical diagnosis. There was, however, very little difficulty in diagnosing free fluid in the pleural cavity by X rays. As the fluid increased in quantity the fluid line became more and more opaque, and it could also be seen whether the fluid was free in the pleural cavity or not. The condition of abscess of the lung was extremely difficult to demonstrate by X rays, and a great deal depended on the position of the abscess. But in some cases it was possible to make a definite diagnosis of abscess, as even if the cavity itself was not shown, the area round it was. It was not, of course, possible to diagnose an abscess which was lying under an effusion, and the greatest difficulty was experienced in cases where there was fluid and consolidation, as one obscured the other.

Dr. C. J. MURPHY said that within a year he had had six cases of intrapulmonary sepsis, and he had found that elevation of the foot of the bed was extremely successful.

Mr. **DENIS KENNEDY** said he thought empyemata in children and in adults were quite different things. Aspiration relieved the patient during the acute phase, and after this had been done he thought that ordinary drainage for a short time should be sufficient.

Dr. **LEONARD ABRAHAMSON** said that he had recently treated two cases of intrathoracic suppuration. The first was a case of purulent pericarditis in a child who was admitted to hospital with an abscess on the hip, and when the abscess was opened the pus was found to be due to *Staphylococcus aureus*. The abscess had been noticed after the child had had a fall, but before the fall the child had had a gum-boil, and on examination it was found that there was an abscess over one of the teeth. The pus in this was also found to be due to *Staphylococcus aureus*. The pericarditis could not be treated by surgery, as the patient was too ill. The second case was an alcoholic man who developed pneumonia. An abscess formed on the lung, and pus was aspirated from it. The whole of the chest wall showed interstitial empyema. On incision the muscles of the chest wall were found to be full of pus. They went on suppurating for some time, and then the patient died from exhaustion. He thought that a needle should never be put into the lung unless one was prepared to operate afterwards. If an abscess was towards the upper part of the lung he thought it should be left alone, but if it was at the base of the lung, then surgery was indicated.

Dr. **H. T. BEWLEY** said that he also felt that aspiratory treatment of empyema was futile in most cases. He had recently seen two cases, both of them children, with pure pneumococcic empyema. At first, on aspiration, opalescent fluid was removed, but this re-accumulated, and on the second occasion pure pus was removed. Neither of these cases benefited by aspiration, but they were both operated on and were quite well within a fortnight.

Reviews and Notices of Books.

PEDIATRICS.

By Various Authors. Edited by ISAAC A. ABT, M.D., Professor of Diseases of Children, Northwestern University Medical School, Chicago. London and Philadelphia: W. B. Saunders Co. 1923–1924. Vol. I., pp. 1240; Vol. II., pp. 1023; Vol. III., pp. 1051. 8 Vols. £18 per set.

THIS encyclopædia of the diseases of children, prepared for the practitioner, the student, and teacher, is composed of a series of monographs by writers with special knowledge of their subject. An attempt has been made to cover not only the internal diseases of children, but also subjects of surgical interest, and this encyclopædia may come to displace the only other encyclopædia on children's diseases written in English—that by Keating prepared in 1889.

Vol. I. starts with a monograph on the history of medicine by Fielding H. Garrison, wherein the history of pædiatrics is traced to the present time. It will be of some interest to readers in this country to discover which are the names among British and foreign pædiatricians which the writer—an American—considers of sufficient note to deserve mention; certainly many names which one would have expected to find have been omitted. After a chapter on Congenital and Acquired Predispositions and Heredity by Clarence Little, and one summarising with great care and numerous illustrations the Anatomy of the Infant and Child by Richard E. Scammon, T. Brailsford Robertson deals with Growth and Development. He gives an admirable description of the general characteristics of the growth process, and points out that the growth of children and animals takes place in spurts, separated more or less distinctly from one another by periods of languid growth. In the first half of gestation growth is slow; the second half shows extraordinarily rapid accretion of tissue which continues up to the first year of extra-uterine life, when a slackening of growth occurs. At the third, fourth, and fifth years the pace of growth increases greatly, is followed by a pause, and then once more extreme rapidity of growth is shown during adolescence. Reference is made to vitamins and general environment as factors influencing growth. Chapter V. consists of a discussion by John R. Murlin, of Rochester, N.Y., on the Physiology of Metabolism in Infancy and Childhood. For this chapter alone this book is worth purchasing, so clear and complete are its contents.

Jesse McClendon deals with the Application of Physical Chemistry to the Physiology of Childhood. This short monograph covers the subject of the hydrogen-ion concentration of the alimentary tract, the blood, and other body fluids. The Hygiene of the Home is then discussed by Walter Reeve Ramsey, and the Hygiene of the School Age by Josephine E. Young, of Chicago. An excellent portion of this chapter touches on mental hygiene, when Dr. Young shows a clear insight into the problems of the school medical officers of this country as well as those of her own. A few pages are devoted to the teaching of sex hygiene and sex delinquency. The chapter concludes with notes on the hygiene of instruction of writing, reading, the hygiene of the kindergarten, manual training, play, clothing, school architecture, heating and ventilation, swimming-pools, and open-air schools. These latter are in many cases established on the roofs of the tall buildings in some of the crowded cities and great benefit is derived by the children. The Hygiene of Infants is dealt with by W. R. Ramsey, and Climatotherapy by F. L. Wakeham. A chapter by H. Winnett Orr on Hygiene of Crippled Children completes this volume.

Chapter XII., which opens Vol II., consists of a monograph on the Mortalities of Infancy by R. A. Bolt. History-taking and Physical Examination of Infants and Children is then discussed by Mark Jampolis, and Cerebro-spinal Fluid by Abraham Levinson. Roentgenology in Pediatrics is admirably dealt with by F. C. Rodda. More than 60 photographs illustrate the diagnosis of tuberculosis, foreign body, atresia, &c., by this means. No detailed mention, however, is made of the aid which may be gained from X rays in the diagnosis of congenital pyloric stenosis or duodenal stenosis, and the photographs are confined to the thorax. In Chapter XVI. John Diven discourses in somewhat aimless fashion on Peculiarities of Disease in Childhood. This chapter would seem to be redundant. On the other hand, another general survey on Prophylaxis and Treatment, by L. R. De Buys, is excellent. The author affirms that the diseases of the newly born belong to the pædiatrician, and that the obstetric interest in the mother may deprive the child of the special consideration which it should receive were it placed immediately under the care of a trained pædiatrician.

Therapeutics are discussed under the headings of Aerotherapy, Climato-therapy, Dietotherapy, and Psychotherapy. Under Therapeutic Technique, Gastric Lavage, Enemas, Lumbar Puncture, &c., are described and illustrated. Drugs are classified according to their action, and a list occupying 20 pages give doses suitable for children aged 6 months, 1 year, 18 months, 2 years, and 3 years. This chapter will be of the utmost service to the young pædiatrician. Heliotherapy is dealt with adequately by Henry Dietrich, and Diseases of the New Born by N. O. Pearce. Then follows a chapter on the Premature Infant by Julius H. Hess, which is one of the most complete monographs on the subject which we have had the good fortune to read, for the author has an intimate first-hand knowledge of his subject. Several pages are devoted to the physiology of the premature infant, followed by an account of the pathological lesions and defects common in these infants. A full description of the requirements of a hospital nursery unit should be especially valuable to those hospitals contemplating the addition of cots. Hess believes that the outlook for premature infants on anything but breast milk is extremely poor. Prognosis as to life and future mentality are fully discussed. The following three chapters deal with feeding problems. The Chemistry and Biology of Milk, Breast Feeding and Nutrition, and the Artificial Feeding of Infants, by J. Sedgwick and W. Cole, point out that "through creating the proper demand on the breast we can in all cases produce some breast milk for every child at least for a time"; and this statement will nowadays be generally accepted as correct. It is interesting to note that the authors do not consider that the mother's milk-supply is affected by emotional upsets, only indirectly in so far as her general nutrition is affected. J. Brennemann cites the well-known fact that if only a small amount of human milk is added to the food of an artificially fed baby, the baby will tend to thrive as though fed only upon the breast. Many pages are devoted to the physiological behaviour of the different food elements of cows' milk as compared with those of human milk and their modification and adaptation in the artificial feeding of infants. This author considers that starch may be given to an infant in small amounts from the second month, and that the benefit following its use is due to the prevention of large curd formation. The behaviour of protein is discussed at some length, and the author would not place at its door the many ills which some of the most modern pædiatricians would attribute to this element.

A chapter on Diabetes Mellitus contains a too meagre description of the use of insulin. Diabetes Insipidus, Sea-sickness, and Beri-beri are ably dealt with. In the chapter on Acidosis, by John Howland and W. McKim Marriott, of St. Louis, a difficult subject is dealt with in a most able manner. T. C. Hempelmann, who discusses Obesity, lays little stress on the subject of hypopituitarism or Fröhlich's syndrome, but is otherwise helpful. Chapters on Infantile Scurvy, Rickets, and Pellagra follow, and the volume is concluded by a discussion on Constitutional Diathesis of Childhood, and a note on Acrodynia.

In Vol. III. the study of gastro-intestinal physiology and pathology leads naturally to a full discussion of nutritional and digestive disturbances. Lesions of the mouth, tongue, nose, and pharynx, congenital and acquired, are excellently described—the chapter on orthodontia or facial orthopædics being noteworthy. Diseases of the glands associated with the intestinal tract receive attention, and eight chapters on the investigation of normal and abnormal conditions of the respiratory tract conclude a volume that comes well up to the standard of those previously issued.

Never before in any series of monographs on children's diseases in English has an attempt been made to cover the ground with such thoroughness and at the same time to preserve such clearness of outlook. Success has been achieved by careful choice of the writers, and by the fact that their individual viewpoints have been preserved. Those who require to refer constantly to literature on pædiatrics will do well to supply themselves with these volumes.

Diseases of the Rectum and Colon.

By P. Lockhart-Mummery, F.R.C.S. Eng., M.B., B.C. Cantab., Senior Surgeon to St. Mark's Hospital for Cancer, Fistula, and Other Diseases of the Rectum. London: Baillière, Tindall and Cox. 1923. Pp. 872. 25*s.*

As the author points out in his preface, this new publication takes the place of two former ones, one on diseases of the rectum and the other on diseases of the colon. The combination of the two books in one volume avoids much repetition, since it is impossible logically to separate diseases of an organ as a whole from those of its terminal part. The new volume, in which the whole subject has been revised, will, we think, become one of the standard English books upon the subject. It is full, well illustrated, and eminently readable, although there are indications that the earlier chapters have been less carefully prepared than the later ones. The great wealth of clinical material at St. Mark's Hospital has caused the author to regard it as unnecessary to quote the experience of other surgeons at other hospitals; references to other works are very scanty. This is a matter of less moment in so far as the practice at St. Mark's Hospital is now very generally followed, except, perhaps, in one particular, that exception being the operative treatment of cancer of the rectum. Mr. Lockhart-Mummery advances cogent reasons for preferring the perineal to the abdomino-perineal excision, the chief of these being the undeniably much higher mortality of the latter operation. The abdomino-perineal operation is admirably described and cases of his own are quoted by the author, but the reader is left somewhat in doubt as to what proportion of cases and which cases call for this very drastic procedure. One is given the impression that the abdomino-perineal operation is now very rarely performed at St. Mark's Hospital owing to the comparative success of the perineal operation in the author's hands. In this chapter the lack of a more extensive review of other surgeons' work is felt.

The book will be useful both to general practitioners and to medical students, and especially so to the general surgeon who is called upon to operate in circumstances where his special experience has not lain.

Diagnostische und Therapeutische Irrtümer und deren Verhütung.

Vol. II.: "Psychiatrie." By Geh. Med.-Rat. Prof. Dr. E. Meyer, Direktor der Psychiatrischen und Nervenklinik der Universität in Königsberg. Second edition. Leipzig: Georg Thieme. 1923. Pp. 119.

As may be gathered from the title of the series in which it appears, Dr. Meyer's publication is a manual of differential diagnosis in mental disease. The neurological aspect is particularly emphasised, very detailed considerations of physical signs being given. By far the longest chapter is devoted to the diagnosis of dementia præcox.

L'Année Psychologique.

23^{me} année. Paris: Librairie Félix Alcan. 1923. Pp. 644. Fr.40.

With this number is resumed the publication of a useful annual. It opens with five original monographs on experimental psychology by French writers, proceeding then to a critical analysis of the world literature for the year ending in October, 1922. Applying an obvious test, one finds that little of note in the Transactions of English societies or in specialist journals has escaped mention. A gap in scientific records is filled by a bibliography of German writings from 1914 to 1920.

Psycho-analysis is regarded as outside the sphere of psychology; except for a reference to Raymond de Saussure's book, no information is given as to psycho-analytical literature, and this limits the usefulness of the publication; otherwise it is a work of reference which will be of value to investigators and students of all nationalities.

Right Food the Right Remedy.

By Charles C. Froude, B.Sc. With an Introduction by Royal S. Copeland, A.M., M.D., formerly Commissioner of Public Health, New York. London: Methuen and Co. 1924. Pp. 301. 7*s.* 6*d.*

We are not at all favourably impressed by this book. It is a popular book, and as such, we cannot and do not expect it to be very profound. But even in a book for the multitude, we do expect the author to display some knowledge of the modern aspect of his subject, and we look for that feature in vain in the work that lies before us. One passage may be quoted as typical of its contents (p. 55): "Improper elimination also means that harmful deposits are often formed within the body. Many of the more hearty and staple foods—such as meat, eggs, bread, and the legumes—often decompose before they can be digested, due to their deficiency in food salts—the salts which are antiseptic or antifermentic. The raw fruits and raw vegetables are rich in antiseptic or antifermentic food salts, and if eaten with the staple or hearty foods, will lessen, or counteract, this decomposition. . . . . The question receives consideration under the name of 'vitamins' and other terms, but it is the same truth which Dr. J. H. Tilden, since he brought it out many years ago, has been teaching and practising." What are these "antiseptic or antifermentic food salts"? And even if such exist why does the author claim that they have any relation to the vitamins? We cannot even guess at the meaning.

DIE ZWILLINGSPATHOLOGIE.

Ihre Bedeutung, ihre Methodik, ihre bisherigen Ergebnisse. Von Dr. HERMANN WERNER SIEMENS, Privatdozent für Dermatologie an der Universität München. Berlin: Julius Springer. 1924. Pp. 103. $1.90.

As the author somewhat pathetically remarks in his first chapter, "mit dem Menschen kann man keine Vererbungs-experimente machen." This being the case, the assessment of the relative importance of hereditary and environmental factors is a matter of much greater difficulty in man than in animals and plants. In twins, at any rate of the uniovular variety, Nature has provided pairs of individuals who, so far as heredity is concerned, may be regarded as having started existence under identical circumstances; any differences between the members of such a pair may be looked upon as the effects of factors other than heredity. From the psychological and sociological standpoint, observations as to differences in mentality and character between twins are on this account of particular interest. In this book the author has endeavoured to extend the method to pathology and, in fact, to establish a whole system of "Zwillingspathologie." It is, of course, obvious that the subject is merely a part of the whole pathology of heredity, in the laying of the foundations of which Nettleship and other English observers long ago did such important work. The author gives due credit to the work of the pioneers, and has added many observations of his own, mostly, it must be admitted, of a rather negative nature. It is difficult, for instance, to comprehend the value of the observation that of two twins one died of chronic pancreatitis at the age of 35, and the other did not. However, that knowledge may grow, someone, presumably, has to note these things.

RELIGION AND THE NEW PSYCHOLOGY.

And Other Addresses. By N. BISHOP HARMAN, M.A., M.B., B.Ch. Cantab., F.R.C.S. Eng. London: The Lindsey Press. 1924. 2*s.* 6*d.*

IN this little book Mr. Bishop Harman has attempted to state from a medical standpoint some of the views of life current to-day in our society, and he uses a wide experience of affairs in a comparison of these views with religious experiences, and particularly with religious intuitions, which, by as much as they are hard to define, possess also a corresponding influence over men's minds. The book contains three essays or addresses and ends with a very brief but dignified religious confession. As Mr. Harman says in the opening paper, an address given before the National Conference of Unitarian and Free Christian Churches and afterwards published in *The Hibbert Journal*, it is necessary, if we are to understand the fundamentals of modern psychology, to have a working knowledge of biology. He arrives at the conclusion that the soul conception, if it cannot be proved, cannot be disproved, while pointing out that belief in that conception is fundamental in the peoples who have sought to guide their steps by the light of intelligence.

The book is short and simple, though dealing with the most difficult problem before us all; it should be really helpful.

TO VENICE AND BACK IN A TWO-SEATER.

By E. HALFORD ROSS. London: Cassell and Co., Ltd. 1924. Pp. 240. 6*s.*

WE should not have thought that the intention of the author and his wife to spend a holiday on the Continent with the assistance of a two-seater would have led a large circle of acquaintances to insist that the idea was ridiculous. Surely it has been done before, and surely it will be done again; and possibly the absence of all misadventure, which is remarked upon by Dr. Halford Ross, may encourage others to do likewise and to pass along similar routes. Certainly, the places visited in the itinerary undertaken by Dr. Ross and his wife are well worth seeing, and while people who travel on the Continent with any regularity will have visited many of them, most of them possess an attraction as vivid for old friends as for new visitors. The chronicle makes the kind of rambling diary which is agreeable reading for the personal friends of a traveller, when quite small beer acquires a flavour from private knowledge of how so and so will take such and such an event—the thing that is not worth recording publicly may have a particular application in the case of a particular chronicler. Occasionally this little book is funny in a primitive way, and occasionally the author is unnecessarily informative, for surely quite a lot of people know who Rousseau was and what is the use of circular letters of credit; the comparative size of mortals and mountains has been widely observed, and reflections of a similar character may be found in these artless pages.

Dr. Halford Ross supplies 19 little sketches, many of which are artistic in the way in which they secure their purpose without labour or detail.

JOURNALS.

JOURNAL OF INDUSTRIAL HYGIENE.—Old-time stories of quicksilver mines, where only slaves and convicts could be employed, add interest to a paper in the March issue by Dr. A. Hamilton on the Mercury Mines of California. The metal occurs chiefly as sulphide of mercury or cinnabar, but also as the selenide, the monochloride, the iodide, and the telluride. In some mines "the silver runs free" and is found in droplets, but as these rich mines are hot, over 90° F., the danger from poisoning is too great for them to be worked. In the stress of wartime an attempt was made with serious results to the miners. Cinnabar is reduced by roasting when the metal distills off and is collected in condensers, but it penetrates everything and the men can only escape mercurialism by exerting personal care. Even so cases of poisoning occur from time to time, several of which are described in detail.—The main article in this number is a report on Bakers' Itch by Dr. A. C. Parsons, who investigated this trouble in Great Britain. He finds that an important influence is personal cleanliness, and does not blame any specific influence. Ordinary scabies in many cases has been called bakers' itch. The incidence was found greatest in congested districts and on old-fashioned premises where dough is made by hand, while cases were rare in well-equipped establishments. Contact with sugar and dough in the absence of washing caused skin rashes. Prevention lies in the use of dough machines and in the provision and use of washing facilities. In a few rare cases an intolerance of flour proteins develops, which prevents continuance of employment. The article is well illustrated and contains valuable information.—A capable article upon the difficult subject of sickness insurance statistics, by Dr. L. Teleky, Düsseldorf, completes a truly international number.——In the April issue Miss M. Smith reports on a study in activity and fatigue conducted in the laundry trade. The paper is well illustrated and the data collected by devising tests applicable to the industry are clearly marshalled. Energy as measured by output was found to slow down at the end of the day. Official rest-pauses are reported as beneficial.

The general health of laundry workers was found to be fairly satisfactory.—The occurrence of blastomycosis as a complication of industrial injuries is exemplified by Dr. R. M. Carter from reference to three cases. This condition was first described in America and became known as the Chicago disease. No cases have yet been reported in Great Britain.—Dr. E. L. Kennaway contributes a long and important article on cancer-producing tar and tar-fractions. In it are detailed the results of intensive investigations for determining the noxious factor, but coal-tar presents so complicated a chemistry that the labour of trying out each constituent on mice has been immense. Industrial and experimental evidence agree in incriminating the higher boiling fractions distilling over from 250° to 500° C., but the exact cancer-producing substance has not yet been isolated. Something, however, has been achieved by narrowing down the scope for further research. The way in which field observations in industry and laboratory experiments on animals have been found to accord lends promise to further work on these lines.

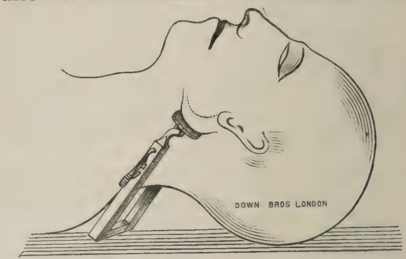
BRITISH JOURNAL OF ANÆSTHESIA.—With the present issue this journal completes its first volume. Dr. Dudley Buxton contributes to this number another of his very readable historical sketches. This deals with Snow and his work on chloroform, and we may heartily endorse the concluding paragraph: "To study Snow's work and follow it by studying the more recent experimental research would, the writer believes, prove most helpful to those who, not being experts, have relegated chloroform to the limbo of bogeydom and so lost the aid of a most valuable asset to their anæsthetic armamentarium."—Mr. S. R. Wilson discusses modern developments in anæsthesia and deals extensively with elaborate preliminary investigations to determine the patient's exact bodily condition and to forecast his behaviour during and after operation and anæsthesia. These investigations are of especial value in relation to myocardial deficiency.—The useful abstracts of current literature on anæsthesia are continued, and an index is supplied to the completed volume, on which its editor, Dr. H. M. Cohen, may be congratulated.

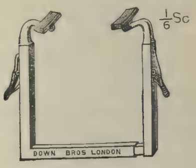
JOURNAL OF THE ROYAL ARMY MEDICAL CORPS, March and April, 1924.—In the opening article of the issue for March Col. R. S. Hannay discusses a "manœuvre exercise," and Dr. H. M. Woodcock concludes his paper on the Rickettsia bodies.—Maj.-Gen. W. W. O. Beveridge publishes his presidential address to the Army, Navy, and Air Force Group of the Society of Medical Officers of Health, wherein he mentions many of the advances in military hygiene made since the war. The Director of Hygiene at the War Office is now responsible not only for the health of the accepted recruit, but for his medical selection and for his being watched during his training. It is hoped there will soon be a standard of mental capacity; at present some 60 per cent. of the recruits offering themselves are taken. During their five months at the depôts they are regularly weighed, and usually gain 10 lb., but lose weight if sick in hospital or when absent without leave. In future wars a sanitary section will be allotted to each division, and will be commanded by an R.A.M.C. officer, specially trained, but not necessarily a medical officer. The N.C.O.'s are termed sergeant or corporal sanitary inspectors, and the sections include tradesmen as bricklayers, carpenters, and sign-painters. The health of the army is improving, the death-rate is down to pre-war figures, venereal disease is down to 25 and scabies to 8 per 1000. Present-day temperance is responsible for much improvement in health and physique.——In the April issue Lieut.-Col. C. W. Holden gives an interesting account of the anti-malarial measures undertaken by the 22nd Division on the Macedonian front along Lake Doiran in the spring of 1918, specially stressing cresol as a better larvicide than oil.—Maj. W. H. B. Ritchie has a paper on the education of the corps, pleading for a general staff for the Army Medical Services to deal with war problems, operations, and training.—The Danish treatment of scabies, introduced by Dr. Svend Lomhelt, has been adopted as the standard treatment in the British Army, and has shortened time in hospital by a half or even more. The ointment, freshly made of sulphide of potassium and zinc in vaseline, lanoline, and paraffin, is smeared thoroughly over the skin, but is not rubbed in. There is no dermatitis, the parasites are at once killed, and the patients are cured in 24 hours. "No relapses have occurred" is the report from the Royal Herbert Hospital at Woolwich.—Col. S. F. Clark describes what he saw in a trip round Southern Arabia, including Socotra, which many have seen but few have visited.

New Inventions.

APPARATUS FOR SUPPORTING THE JAW DURING ANÆSTHESIA.

THIS instrument has been designed to facilitate the maintenance of an adequate airway in cases in which the manual support of the jaw by the anæsthetist is inconvenient or demands an abnormal amount of attention. In such cases the mechanical support of the jaw frees the anæsthetist's hands from performing a purely mechanical function, and allows him to concentrate more closely on the condition of the patient. This instrument will be found useful in operations on the eye, when complete immobility of the head is essential.





The support consists of two upright metal bars, the length of which can be varied at will, bent inwards at their upper extremities to form sockets in which the angles of the jaw rest. The sockets are covered with soft rubber pads to prevent pressure injury to the skin, and are capable of slight movements on a lateral and a vertical axis so that they can be more accurately adjusted to the contour of the bone. The lower extremities of the uprights are connected together by a transverse bar which can be adjusted to any length according to the width of the patient's neck. When the instrument is in use this bar rests upon the table just behind the patient's shoulders, which prevent it from slipping forward. The pressure on the angle of the jaw is then exerted in the proper direction—e.g., backwards and upwards—and by the correct adjustment of the length of the upright bars the force can be so regulated that it is just sufficient to keep the jaw in position, and no more. The instrument can be adjusted to the patient in a few seconds and when once applied does not need further attention. The appliance is, of course, limited to operations in which the patient is in the dorsal position.

Messrs. Down Bros., Ltd., London, are the makers.

THE LANCET.

LONDON: SATURDAY, MAY 31, 1924.

THE LISTER INSTITUTE.

The need of a combined histological and serological effort in order to elucidate the mechanism of natural defence to infection was stressed by Prof. J. C. G. Ledingham in his presidential address[1] to the Pathological Section of the Royal Society of Medicine in 1922, and in the annual report for 1924 of the Lister Institute of Preventive Medicine the results of some of his investigations on these lines are indicated. With a view to determining the validity of alleged specific affinities or tropisms of certain viruses for particular tissues, he has recently been studying the tissue changes at the site of inoculation in vaccinia, the virus having been introduced intracutaneously. It is not stated what animal was used. It has been ascertained that it is the reticulo-endothelium system which is primarily involved, the epidermis escaping unless the horny layer is sufficiently permeable to allow the passage of the exudate to the surface to form a scab or vesicle, in which case the epidermis is only secondarily implicated. The surgical removal of skin lesions at daily intervals has enabled the progressive changes to be studied from the day of infection onwards. In the same department Dr. J. A. Arkwright, working with Dr. S. S. Zilva, is studying the influence of diet deficiencies on the inflammatory response of skin and subcutaneous tissues to bacterial and toxic stimuli. This work also should have an important bearing on the solution of problems of natural immunity. Among the many other researches under weigh in this (the bacteriological) department are those of Dr. E. E. Atkin on the relation between differences in serological grouping as exhibited by strains of meningococci and gonococci with cultural peculiarities, and an attempt to elucidate the histogenetic relationships of the mammalian blood platelet by Dr. S. P. Bedson and Miss M. E. Johnston. With Dr. Zilva, Dr. Bedson has carried out further experiments on the question of platelet reduction in vitamin-A deficiency, but has failed to confirm the alleged grave implication of these elements. Dr. E. H. Lepper and Dr. M. L. Cowan have outlined work undertaken by them at this Institute at a recent meeting of a society reported on p. 1105 of this issue of The Lancet.

In the department of biochemistry, directed by Prof. A. Harden, patient work on the accessory food substances had laid bare certain intriguing and crucial facts, though the isolation of these substances has not yet been achieved. For example, using rats as the experimental animals, it has been found that while wort usually contains the antineuritic vitamin, it is absent from the finished beer. Significant progress has been made by Dr. Zilva in the fractionisation of the antiscorbutic factor in lemon-juice. It is now possible to reduce the total solids of lemon-juice from about 9 per cent. to about 0·04 per cent., without appreciably diminishing the antiscorbutic activity. A method has been devised which renders it possible to store concentrated antiscorbutic preparations without any loss in potency, and successful clinical results have been obtained by the use of such stored preparations. Evidence appears to be accumulating that Prof. E. V. McCollum's conclusion that the growth-promoting and the antirachitic factors are not identical. Inactivation of these two principles by heat and oxygen proceeds at different rates and their quantitative distribution in spinach is also different. Moreover, Dr. R. Wagner and Dr. H. Wimberger, whose clinical studies on rickets in Vienna will shortly appear in our columns, have demonstrated that cod-liver oil, oxidised to the point at which 95 per cent. of the vitamin A is destroyed, possessed therapeutic value against rickets not obviously inferior to that of the untreated oil, thus providing additional evidence for the existence of two separate principles, (1) growth promoting, (2) rickets preventing, in cod-liver oil. The difference in the antirachitic value of milk, as the food conditions of the cow yielding it is changed from pasture to winter fodder and vice versa, were found by Dr. Ethel Luce to be considerable, and Miss M. A. Boas, working with young, growing rats has done complementary observations on the growth-promoting factor which show that cows' milk varies according to the diet of the animal in respect of this factor also. Prof. V. Korenchevsky, with the assistance of Miss M. Carr, has investigated the influence of qualitative deficiencies in the diet given to parent rats upon the number, weight, and composition of the young, concluding that the father's diet before conception has no effect, but that the diet of the mother before conception and during pregnancy influences the number and weight of the litters, but not the percentage of H_2O, Ca, P, and N in the young at birth. The mother evidently sacrifices her own tissues to produce offspring of approximately normal composition. Prof. C. J. Martin, the Director of the Institute, was engaged in the earlier part of the year in experiments to determine the limiting conditions as regards temperature, moisture, and air movement for a man to work at the rate of one-tenth horse-power, which is the performance of a good miner or navvy. The results of his observations were incorporated in a presidential address to the Hygienic Section of the Pan-Pacific Conference held in Sydney, where the feasibility of white labour in the tropics and the hygienic problem of hot mines were discussed. The problem of consistently producing a good diphtheria toxin has continued to occupy the attention of the department for the study and preparation of antitoxic serum; also the search for a more satisfactory method for the standardisation of anti-dysentery serum and for the best way of estimating the therapeutic value of antimeningococcus sera. A new laboratory at Acton, Marazion, Cornwall, has been constructed and equipped, where the preparation and study of antivariolous vaccine will in future be undertaken.

There are still those, however, who doubt the immediate practical value of researches carried on at an institute detached from hospital beds, and protest that work conducted in such institutes tends to become academic. To show how invalid is this argument, we may select from various parts of this report a few notes showing clearly that the Director and his colleagues are alert and eager to test experimentally any new or revived method that might be of value in therapeutics. Several remedies appear to have been tried out on sick animals, or experiments have been devised to test the validity of the theory on which their administration is based. Dr. A. L. Schütze has in the past nine months tested the reputed therapeutic value of Dreyer's diaplyte vaccine on tuberculous guinea-pigs. No evidence has been obtained that the course of the disease in these animals is favourably modified by this treatment. Again, the sodium salts of various fatty acids in soap form have been claimed to exert favourable and healing action on diseases due to acid-fast organisms (tuberculosis and leprosy). The selective action of fatty acids on acid-fast bacilli is striking, but as a result of investigations on the potency of a series of these acids from a variety of sources in inhibiting the growth of tuberculosis in artificial culture it does not appear that any particular soaps are more efficient than others in this respect, equally good inhibiting results being obtained with derivatives of cotton-seed oil as with chaulmoogra oil. Miss JOHNSTON has been engaged on a problem which intimately concerns the practice of serum therapy and serum prophylaxis—that is, the influence of the previous injection of serum, whether normal or immune, on the effective action of a subsequent injection. Her results show that the loss of effective action from a subsequent dose which may occur when a previous dose of normal serum has been given can be explained solely by the development of antibodies to the original serum proteins injected. The immunity is not of the nature of an anti-antibody reaction. Dr. A. HUNTER BROWN is devoting himself to the study of the efficiency of immunisation methods by the cutaneous route, for which claims have recently been made by BESREDKA; and lastly, it has been found that the value of antimeningococcus serum appears to depend not only on type, but also largely on the strain used for immunisation of the horses; and it has been decided in future to use as many unrelated strains as possible for the production of therapeutic sera.

---

[1] The Lancet, 1922, ii., 898.

We have only touched here upon a few of the scientific activities of the Institute. It should be added that the Medical Research Council has availed itself freely of these activities, providing seven whole-time workers and subsidising others, besides furnishing the salaries of the staff of the National Collection of Type Cultures which is housed in the Institute. Others whose business or pleasure it is to subsidise medical research on behalf of the community should not fail to note the excellent work being carried on at the Lister Institute of Preventive Medicine.

◆

FUTURE OF THE INDIAN MEDICAL SERVICE.

THE Royal Commission appointed last year, with Viscount LEE as chairman, to inquire into the higher ranks of civil service in India has just issued its report.[1] The Commissioners were asked to inquire into the general conditions of the various services, into the possibility of transference of any of their present functions from the central to provincial government, and into the whole question of ensuring and maintaining the recruitment of Europeans and Indians for those services. They were instructed to assume the necessity for maintaining a standard of administration in conformity with the responsibility of the Crown and the acceptance of the declared policy of Parliament increasingly to associate Indians in every branch of the administration.

As far as the Indian Medical Service is concerned, the recommendations of the Commission can be summarised almost in a sentence. Contrary to the recommendation of the Verney-Lovett Committee, the Commission recognises that the medical needs of both the British and Indian armies in India should be provided for in future by the Royal Army Medical Corps (India) which should absorb the Indian Medical Service, no attempt being made to perpetuate that service as at present constituted. This recommendation is in accordance with the scheme elaborated by the late Sir CHARLES BURTCHAELL in 1919, and printed at length as an appendix to the present report. At the same time, a new civil medical service is to be constituted in each province recruited by competitive examinations held both in England and India. To meet the medical needs of British officers in the civil service and their families a minimum number of British officers is to be maintained in this civil medical service, the limit to be prescribed for each province by the Secretary of State, on whom in the last resort is to rest the responsibility for their maintenance. Of this British element, one half, or the number required for the military reserve (whichever is the larger), is to be reserved for British officers seconded from the R.A.M.C., the remainder being those succeeding in competitive examination. It is further recommended that, subject to the existing rights of present members of the Indian Medical Service, all scientific chairs in Government colleges and hospitals shall be thrown open to all candidates, the clinical chairs alone being reserved for members of the civil medical services so far as suitable candidates are available.

The report recognises the great part which the Indian Medical Service in the past has played in the civil life of the country, as the chief agent in spreading Western ideas of medicine, surgery, and sanitation, and as a centre of original research; but the difficulty in securing British recruits of late years has been very great. At the present moment there is, in fact, a shortage on the civil side of no less than 57 officers in the authorised cadre of 420. The Commission gives reasons for its belief that the Burtchaell scheme may be so adapted as to meet the requirements of each province for a separate civil medical service, as well as to provide the necessary nucleus of British medical officers, which is regarded as vital to the needs and contentment of the British civil service in India. The Commission calls for the establishment without delay of the statutory Public Service Commission, whose task it will be to undertake the recruitment of personnel, as well as to establish and maintain proper standards of qualification for admission. Indianisation of the medical service of India, it is recognised, must be a long and steady process. But the position has altered to such an extent from the time of the Islington Commission that the question is no longer how many Indians should be admitted into the service, but what is the minimum number of Englishmen which must still be recruited.

THE WHITE MAN IN THE TROPICS.

THAT a tropical climate has a depressing or an injurious effect on the white colonist is generally acknowledged. Prof. C. EIJKMAN, in a recent lecture[1] delivered in London, put the position aptly: "The state of weariness and listlessness coupled with psychical irritability, to which the European gradually becomes subject in the tropics, has always reminded me of the syndrome to which has been given the name of neurasthenia or nervous exhaustion." A similar conclusion—i.e., that the chief stress of a tropical climate falls on the nervous system—was reached by Dr. ANDREW BALFOUR in a series of lectures delivered last

[1] THE LANCET, May 3rd, 1924, p. 887.

June at St. Bartholomew's Hospital. We have, therefore, to deal with this effect even if there is no disease due to parasite or bacterium. It is difficult, however, to elucidate how or why such nervous symptoms arise. Anæmia is not responsible, since Prof. EIJKMAN states there is no purely physiological anæmia of hot countries. He also failed to detect any difference between tropical and temperate climates as regards chemical heat regulation of the body—that is, in metabolism and heat production. The food requirement is, with about similar labour conditions, as great in hot as in temperate climates. Prof. EIJKMAN'S own basal metabolism, examined in winter in Holland at room temperature of 9° C., appeared to be the same as it had been two years before in a temperature of 27·5° C. in Batavia. Other observers, however, have obtained higher figures for temperate climates than for tropical climates. Of interest in this connexion are the researches carried out by Dr. LEONARD HILL and his co-workers on the effects of exposure of the body to variations in rate of external cooling as measured by the kata-thermometer. Their results showed that such variations in temperature as Prof. EIJKMAN employed—i.e., 9° C. and 27·5° C.—were not sufficient to affect metabolism of a clothed man in still air; and that the exposure of the clothed body to two or three times this rate of cooling caused a definite rise of metabolism. They also found that exposure of the naked body to the open air during summer in England increased bodily metabolism by 20 per cent. or more.

Dr. LEONARD HILL has pointed out that many people in temperate climates were really living in a tropical climate through overclothing their bodies and shutting themselves up indoors. One would hardly expect the metabolism of such individuals to be higher in the temperate than in the tropical zone. Dr. HILL, indeed, advocates greater exposure of the body to open air for the very purpose of counteracting national deterioration. Prof. EIJKMAN considered that observations carried out whilst doing heavy muscular work might throw more light on the subject; he obtained some evidence from a few experiments that during heavy work efficiency is lowered under warm conditions. He has also obtained definite evidence of differences in behaviour of the sweating mechanisms of white and coloured man, in other words, in the physical—as opposed to the chemical—regulation of body heat. He found that although Europeans and Malayans had about the same number of sweat glands per unit of skin surface, the Europeans lost more water, and therefore more heat, by insensible perspiration than the Malayans; on the other hand, the Malayans lost more heat by conduction and convection; these differences were independent of the quantity of water taken. The chief differences between the two races consisted, therefore, in the function of the skin; the coloured man was by his pigmentation better protected against the chemically active rays of the sun and he was not so subjected to excessive sweating. Water regulation may therefore play a leading part, but one must guard against theorising in this direction at the present stage. Some other recent researches on this subject are to the point. J. S. HALDANE and K. N. MOSS found that great sweating depleted the body of sodium and potassium salts. H. G. BARBOUR'S researches in America on the mobilisation of water indicate that blood dilution occurred in response to external heat and thus aided sweating processes, whereas exposure to cold led to a concentration of the circulating medium, the anhydræmia promoting sparing of heat. Prof. EIJKMAN suggested that acclimatisation might be more rapid for the white man if he followed the native in his frugality both in respect to food and drink, in his calm resigned view of life, and in his rule of *festina lente*. However, in such a case the white man would lose some of his characteristics, since, to him, as Prof. EIJKMAN said, "Health is not a mere negation of illness, it also implies something positive. The full use and control of the mental and physical functions, a vigorous constitution, and a considerable amount of bodily well-being—those characterise the healthy man. Much of this the sojourner in the tropics lacks, though he may be exempt from illness. This especially applies to the white man, and the consolation that he is a 'permanent summerman' cannot make up for this deficiency." Such are the difficulties the future will have to overcome if the tropics are to be colonised by the white man as we now know him.

According to Prof. EIJKMAN, who was the first director of the laboratories at Weltevreden in Java, the researches on this subject carried out during the past 30 years in the Dutch East Indies tend to disprove all theories so far enunciated to explain the depressing effect of a tropical climate on the nervous system of the white man. If we ourselves may be permitted to theorise, we would suggest that the monotony of atmospheric conditions in the tropics may stress the nervous system. In those places where there is little difference between atmospheric conditions for day and night and for seasons, the nervous system is continually at work supervising loss of body heat, whereas in climates with seasonal changes and day and night changes, during the cold periods the nervous system has the opposite function—sparing of heat—to control. Change of function may involve rest for one or other part of the nervous mechanisms. Telegraphists' cramp, for instance, is not a true cramp, but an hysterical spasm, and is rectified by change of work. Similarly, the frequent change of atmospheric conditions might prevent the nervous defects due to tropical monotony.

◆

MEDICAL PROTECTION.

NO practitioner is safe against becoming involved in very costly litigation arising out of his practice, and no amount of care and skill can render him immune against attack by unscrupulous or wrong-headed persons. Yet at a trivial cost protection can be obtained, and it is to be regretted that there are several thousands of practitioners who have not yet availed themselves of this line of defence. The London and Counties Medical Protection Society, one of the principal defence organisations, held its annual meeting of members recently, when the Council submitted a report of a successful year's work, including a steady increase in membership and financial resources. During the year 1923 the number of applications from members asking for advice and assistance was 662 as compared with 645 for 1922 and 465 for 1921. The results of cases in which litigation occurred were satisfactory, but in the great majority of cases settlement was obtained without litigation. The Council recorded with deep regret the deaths of two of the trustees of the Society's reserve fund—Sir James Reid and Sir John Tweedy to whom the Society was greatly indebted. Sir Anthony Bowlby and Sir Harry Baldwin have undertaken to act in their places. The marked increase over all previous years of cases which passed through the solicitors' hands during the past year indicates that the value of the Society is being more widely appreciated. Three hundred cases have been dealt with in this way, and of these a considerable number were satisfactorily disposed of by the general secretary without further legal proceedings. The year is particularly noticeable for the very small number of litigious cases which have actually gone to trial.

The experiences of the Medical Defence Union and the Medical Protection Society alike show that the questions and appeals arising from the National Health Insurance Regulations are markedly on the increase, and the solicitors to the Society warn panel practitioners thus: "The authorities, it would seem, are demanding from panel practitioners almost academic adherence to their terms of service and medical benefit regulations, and panel practitioners cannot be too careful in their strict adherence to them, as otherwise they may find that through a purely technical breach they are penalised in a substantial amount." We record elsewhere the results of three official inquiries held into the conduct of panel practitioners where the lapses cannot be categorised in this way. Such cases are very rare, so that they form a foundation for a distrust of panel practice which is quite unjustified. It should be pointed out that, in two of the cases at any rate, the charges were supported by animus, and in certain materials could hardly have been sustained before a jury—a reflection which detracts in no way from the fairness or acumen of the official tribunal in the discharge of very difficult and responsible work. The London and Counties Medical Protection Society urges, in the event of any trouble of this sort, that their members should inform the Society immediately, as the Society has in many cases been embarrassed in its efforts on a member's behalf by the matter coming to its notice when the position had already been complicated by unwise action on the part of the member. A large number of charges of negligence and unskilfulness are dealt with by the Society for its members every year. Many of them are mere excuses for not paying for medical services, or pretexts for attempts to extort money. Some are due to misunderstanding or mistaken ideas, and often have no solid foundation. The following illustrative case, among many, is quoted in the report:—

> A member received a solicitor's letter accusing him, or the doctor who assisted him, of having dropped chloroform into the eye of a patient during her confinement. It was stated that the patient's eye had been damaged and blindness caused. After inquiry, the solicitor was informed that there was no reason to suppose that any chloroform had been dropped into the patient's eye and that the eye affection—interstitial keratitis—from which the patient suffered could not have been caused in the way suggested. Nothing more was heard of the complaint.

The treatment of fractured bones gives rise to many claims for damages every year, and members are strongly advised to insist as early as possible upon an X ray examination in all cases of injury where a fracture or dislocation has been, or may have been, sustained. When this is refused, or omitted, for any reason, a member should provide himself with clear evidence—preferably in writing—to prove that he was not responsible for the neglect or omission. The report states that complaints continue to be received concerning the niggardly provision contained in the Coroners Act whereby a medical officer of a voluntary hospital is deprived of the statutory fee for making a post-mortem examination and giving evidence at an inquest on the death of a patient dying in such institution. The Society urges the medical profession to lose no opportunity of protesting against the continuance of this injustice.

The report contains much useful and helpful information and advice on the subjects of libel and slander, medical ethics, National Health Insurance, professional secrecy, medical fees, as well as on difficulties which may arise between partners or between principals and assistants. The numerous cases quoted go to show how many and varied are the trials of the practitioner, and how essential it is that he should adequately safeguard himself.

SMOKE CONTROL IN LANCASHIRE.—At a conference held in Manchester on May 19th, convened by the Ministry of Health and presided over by Mr. J. C. Dawes of that department, the chairman stated to the representatives of 85 authorities in Lancashire and Cheshire that the standards governing the emission of black smoke and methods of observation in this area varied very considerably, and that scarcely two districts had fixed the same permissible period. Even the methods of observation were far from uniform. He suggested that without in any way interfering with local autonomy more uniform methods of administration might usefully be adopted. After an address by Dr. Veitch Clark, medical officer of health, and a prolonged discussion, it was decided to appoint a joint committee to investigate the problem as it affects the area. Each county and municipality was to have two representatives and its medical officer of health or some other officer on the committee, and each rural urban authority one representative and the medical officer of health or other representative on it. Dr. Veitch Clark was appointed convener of the joint committee.

Annotations.

"Ne quid nimis."

QUININE AND MALARIA IN EUROPE.

THE supply of quinine is at present an international health problem, for on it depends the extent to which the epidemics of malaria in the Middle East can be controlled. And it is not a very simple problem. The total annual output of quinine has been put at 600 tons and this has been spoken of as a "world shortage." The present price of sulphate of quinine in England is 2*s.* 3*d.* per ounce wholesale as compared with 1*s.* 4*d.* in 1914, and it would appear that at this price the growers can produce more cinchona bark than the market requires. The enhanced price is determined largely by the increased cost of labour and manufacture, and it becomes relatively higher still owing to the very low buying power of the most malarial countries. Inquiry seems to be called for not only as to the possibility of growing more cinchona, but still more to determine the actual controlling factors in the price of quinine to-day and the possibility of using the drug in some cruder and cheaper form. Now, whilst price plays a dominating part, the practical control of malaria depends on a still more complicated factor—that of the distribution and administration of quinine. In the countries of the Middle East, such as Russia, where 75 per cent. of the population (in some districts 90 per cent.) are suffering from malaria, the only practical means of controlling the epidemic at the present time appears to be by the widespread distribution of quinine carefully controlled. It is possible that as these countries become reorganised the extreme isolation of the majority of the villages (which are often 20–30 miles apart) will enable village committees to deal with their districts locally by drainage and other direct methods of attack on the mosquito vector, but the ignorance of the population and their whole mode of life will, it is to be feared, prevent any such practical steps in this generation. Evacuation of highly malarial districts is impossible owing to the fact that these countries depend on the forests, the haunt of malaria, for wood for houses, heating, and transport. Hence the only line of attack that remains open is quinine administration —first, to reduce the number of human reservoirs, and secondly, to enable the peasants to work on the land. For it cannot be doubted that one of the most potent factors in the spread of malaria in Greece, Turkey, and Russia has been the malnutrition of the population. Malaria and malnutrition, due to absence of crops, constitute a vicious circle, which can only be broken by quinine.

The working out of a system of administration is, however, very difficult. The complete absence of hospitals or even doctors over enormous areas, the lack of communication and transport, the extreme ignorance of the population often with lingual misunderstandings thrown in, the size of the areas concerned, the poverty of the Government, and the liability to corruption constitute an almost insuperable barrier to effective anti-malarial work. Not quite insuperable, in view of the successful experiments now being carried out by the Friends' Relief Unit in the Volga valley, and reported by Dr. Melville Mackenzie a few months ago in our own columns.[1] In this highly malarial district the social conditions are broadly similar to those obtaining in Persia, Greece, or Albania. Some two years ago a complete laboratory was sent out from England with a skilled worker who, in addition to the routine work of blood examinations, has trained large numbers of local personnel in the laboratory diagnosis of malaria and in the administration of a malaria clinic. Boys who have finished their high-school training and who would in ordinary course be going up to a university, receive a three months' course of instruction in this laboratory before being sent out into the villages where each opens a malaria clinic. An outfit of stains, microscope, and quinine is supplied to each such centre, with the result that a very effective network of laboratories and clinics is being established throughout the country. Only microscopically positive cases are treated, and a standard individual course of treatment is laid down. Quinine is given over a period of two months, beginning in the first week with 20 g. daily, and among 200,000 cases so treated of which records have been kept there have been no ill-effects. Very few fail to complete their treatment, and the cases of recurrence or, strangely enough, of reinfection in the cases treated are scanty. One doctor only is employed in the organisation, the whole of the remainder of the work being done by an English laboratory worker with Russian assistants trained in the central laboratory.

---

[1] THE LANCET, 1923, ii., 1225.

The success of this piece of work suggests that it will be found wiser to develop a completely separate anti-malaria organisation rather than to try and work through the grossly overcrowded hospitals and overtaxed medical personnel in the few places where these exist.

CHLORINATION OF THE WATER OF SWIMMING BATHS.

ON several occasions recently references have been made in our columns to the danger of the spread of diseases by the water of swimming baths, particularly with respect to infection of the ears and nose. Mr. Walter Edmunds suggested last week, not for the first time, the partial and rather drastic remedy of preventing water from entering the ears during bathing. At a conference of engineers and surveyors in connexion with the congress of the Royal Sanitary Institute at Hull last year, a paper was read on the continuous filtration of the water of swimming baths by Mr. T. Thomas, deputy city engineer of Hull. As the result of the discussion following the reading of the paper a committee of the Sanitary Institute was appointed to investigate the question, and the report of this committee was published in the April issue of the journal of the Institute. The appearance of this report is opportune at the beginning of a new swimming season. The committee received information from 23 towns and also from the manufacturers of plants for the mechanical filtration and aeration of bath water. The conclusions of the committee are broadly as follows: The processes of mechanical aeration and filtration give good results. Without such continuous process the water of swimming baths becomes foul in a day, and excessively foul if retained in the bath for several days. The committee are not satisfied that a mechanically aerated or filtered water is always bacterially safe and suggest that adequate chlorination is desirable in addition. The committee are satisfied that from a financial point of view mechanical filtration and aeration is a sound proposition as compared with the cost of refilling the baths daily or several times a week with clean water. The committee further suggest that where a process of mechanical filtration is adopted the water should nevertheless be changed once every four or six weeks during the summer and at least once in the winter season. Further, the committee think that a strict rule should be adopted that no person be allowed to enter the bath without some preliminary cleansing of the body, and that the shower or other bath needed for the purpose should be in all cases provided. It seems desirable that wide publicity should be given to the report. The management of swimming baths does not always come directly under the purview of the health committee or medical officer of health of the local authority. The Ministry of Health, however, holds inquiries when applications are made for the sanction of loans for expenditure on these filtration plants. There should, therefore, be little difficulty in securing that such plants are efficient. Medical men are impressed with the dangers to health from the impurity of water in swimming baths. We cannot afford to allow the cultivation of an invaluable exercise such as swimming to be interfered with by the impurity of the water. Many education committees, perhaps especially in inland towns, have made praiseworthy efforts to encourage swimming among the school-children. The organisers of physical education appointed during recent years attach great importance to swimming. During the war we learnt a great deal about the purification of water by chlorination. Now it is no exaggeration to say that it is quite possible at a reasonable cost by means of chlorination and filtration to provide a continuously pure water for all the swimming baths in the country. We trust that this matter will be taken up energetically by both the Ministry of Health and the Board of Education.

THE CONDUCT OF INEBRIATE HOMES.

AT a recent meeting of the Medical Council of the Federation of Medical and Allied Services, with representatives of the Church of England Temperance Society, there was a discussion on the Institutional Treatment of Inebriates, when the following resolutions were adopted :—

1. That in the opinion of this Council suitable homes for the treatment of inebriety serve a useful purpose beyond the relief they afford the patients' relatives.
2. Inebriates should only be admitted to institutions for treatment if considered by medical experts suitable cases for such treatment.
3. Boards or committees of management of inebriate institutions should include one or more medical practitioners with expert knowledge of inebriety.
4. Treatment in such institutions should be under the direct supervision and control of medical practitioners experienced in the scientific management of inebriety.
5. Clinical research and psychic treatment are essential to the success of any method adopted in dealing with the conditions.
6. Institutions for the treatment of inebriety should be of sufficient size to justify the employment of experienced resident medical officers.

Though it is not universally held that psychic treatment is essential in all cases of inebriety, and while some inebriates derive more benefit from residence in a small home or altogether away from others suffering from the same complaint, these resolutions as a whole will undoubtedly commend themselves, not only to those who have experience in the treatment of such cases, but to the patients' medical advisers, relatives, and friends. The admission into homes of only suitable cases will eliminate many undesirables, such as mental defectives and the vicious drunkard, who has no intention to abstain from alcohol. The presence in a home of the latter class prejudices the chance of recovery of others who take a serious view of their failing and are earnest in their desire for cure. It is to be hoped that the Church of England Temperance Society will be again able to establish a home for the poorer class of male inebriates for whose treatment there is at present practically no provision, and to receive them either under the Inebriates Act, or without signature before a magistrate, for shorter periods than was at one time considered essential. The Federation of Medical and Allied Services have agreed to provide expert medical opinion to assist the future management of the Society's Inebriate Homes, and this assistance will be of great value, not only in directing treatment, but in helping to determine the length of detention advisable.

EXCITING CAUSES OF EPILEPTIC SEIZURES.

APART altogether from the essential underlying cause of epilepsy, many factors are known to influence the occurrence of attacks in those who suffer from the disease. Little new has been discovered in regard to these factors or their mode of action, but P. Hartenberg[1] has recently cleared the ground with a useful comprehensive review of what is known. The conditions which favour the occurrence of attacks he divides into two groups: (1) physiological

---

[1] Hartenberg: La Presse Médicale, April 30th, 1924, p. 379.

—influences to which the healthy individual is subject—and (2) pathological. Of the physiological factors the most important is sleep, and, in particular, the periods near the beginning and end of the night's rest. But for some patients it is the half hour which follows the awakening that is the most dangerous time; in these cases the attacks occur even after a short sleep during the day, and are independent of the patient's posture during and after the period of sleep. Influences related to the organs of sex come next in the physiological group; of these the catamenia are the most powerful; puberty, too, has an important effect, and sometimes attacks may begin or may recur at the menopause; pregnancy may initiate the attacks, but more often it brings about a remission of them; coitus and masturbation have been considered provocative of fits by some writers. The intake and digestion of food favour attacks in certain patients. Hartenberg is inclined to see in distension of the stomach the essential element in this sub-group; he has not been able to find any evidence that particular proteins are to blame. Changes in the blood-supply of the brain form the fourth class of exciting causes; they may be brought about by stooping, passing into a warm atmosphere, emotion (especially anger), or mental concentration. The pathological exciting causes are practically all concerned with the functions of the alimentary tract—dyspepsia, dilatation of the stomach, enteritis, constipation—the common factor probably being intestinal putrefaction; certain foodstuffs owe their harmfulness to the putrefaction to which they give rise. Hartenberg considers that periods of slight diarrhœa are a very significant sign in epileptics. Endocrine disorders are mentioned as a second pathological sub-group, the evidence that they favour attacks resting on the beneficial effect of certain glandular extracts in a few cases. Treatment of such favouring factors, though it will not cure epilepsy, is of very great influence in ameliorating it.

UROTROPINE IN THE PREVENTION OF POST-OPERATIVE RETENTION OF URINE.

IN 1921 Vogt, of the Gynæcological Hospital in Tübingen, published in *Zentralblatt für Gynäkologie* an account of his observations on the action of urotropine given by intravenous injection. His original object was to obtain some relief from the discomforts of lumbar anæsthesia. He noticed incidentally that patients thus treated with urotropine experienced no difficulty in micturition after operations. Accordingly he gave from 7 to 10 c.cm. of a 40 per cent. solution of urotropine to all his patients suffering from retention of urine after gynæcological operations, and he found that this procedure was uniformly successful, urine being passed by the patients 8 to 12 hours later without the discomforts and dangers of the catheter. In the summer of 1923 Dr. Sten von Stapelmohr, speaking at a meeting of the Association of Scandinavian Surgeons, confirmed these observations. At his hospital in Stockholm he had given urotropine by intravenous injection in about 50 cases, and the many successes achieved were not marred by complications such as hæmaturia. He had also given urotropine by the mouth in large doses, but the results had not been so good, and the action of the urotropine on the evacuation of the bladder had not been so uniform. Another report comes from the University Gynæcological Hospital in Leipzig. The author of this report, Dr. C. Pasch,[1] writes with an experience of 90 cases, 75 of which were complicated by post-operative retention of urine and 15 by post-operative cystitis. As a rule, it was not necessary to inject more than 3 c.cm. of a 40 per cent. solution of urotropine, but it proved advisable to inject at least 5 c.cm. when gynæcological operations had encroached considerably on the bladder. Systematic examinations of the urine were carried out, but in no case did they reveal ill-effects from this treatment. But in 4 per cent. it gave rise to troublesome tenesmus, and in another 4 per cent. it proved ineffective, the services of the catheter being required. As a rule, spontaneous micturition occurred from two to ten hours after an injection. Control observations with the catheter showed that in 72 per cent. of the cases treated the spontaneous evacuation of the bladder was complete. On the other hand, more than half of the patients who were not treated with urotropine did not empty their bladders completely, even when there was no absolute retention, the residual urine in these cases measuring from 10 to 150 c.cm. Dr. Pasch confirms the observation of von Stapelmohr that giving even large doses of urotropine by the mouth is of comparatively little value. A few years ago the disinfectant action of urotropine on the urinary tract was supposed to depend on the liberation of formaldehyde, but the recent investigations of Buzello and others suggest that this explanation may be incorrect.

THE LESSONS OF ANIMAL DISEASES.

PIGLINGS of a few weeks old are very apt to suffer from a disease which has been ascribed in America to cotton-seed meal poisoning. It is characterised mainly by severe anæmia, dyspnœa, dropsical effusions, and liver changes. In the current number of the *Journal of Pathology and Bacteriology* (vol. xxvii., p. 201) and in the *Biochemical Journal* (vol. xvii., p. 204; vol. xviii., pp. 265, 273) Dr. J. P. McGowan and Mr. A. Crichton give a most interesting account of their observations on the condition at the Rowett Research Institute, Aberdeen. As regards causation, they hold that the condition is essentially due to iron deficiency, accentuated in some instances by incomplete foods, such as cotton-seed meal; they show that it may be prevented and cured by feeding iron oxide to the sow. The blood is very anæmic, the percentage of hæmoglobin falling to 20 or 30 per cent. from the 80 per cent. on the human scale which is about normal for young pigs; histologically there are abundant signs of marrow activity. The heart is much dilated and enlarged; there is frequently hydropericardium, though considerable ascites is more constantly found; in animals which more or less recover these effusions into the serous sacs are followed by adhesions which mat the viscera together. Most remarkable are the changes in the liver, where there is necrosis of most of the central parts of the lobules with severe fatty change, which is distributed patchily through the organ and not uniformly. The administration of iron will cure the liver with or without the induction of a perilobular cirrhosis. The other organs show nothing particular. There is evidently much work still to be done in elucidating the pathology of the disease. In particular, the relation of the different lesions to one another is at present quite obscure. But what has been done certainly seems of substantial importance if only for the discovery of a lobular degeneration of the liver with a patchy distribution—a condition we believe to be unknown in human pathology, and forming a connecting link between the necrosis of whole pieces of liver (as in acute atrophy) and the necrosis of parts of every lobule throughout the liver (as in chloroform poisoning). We hope the authors or others will pursue the matter further, and, not content with being able to cure the disease, will work out its pathology in detail.

The classical methods of morbid anatomy and experimental pathology are often neglected, we regret to think, through investigators being satisfied with obtaining an effective practical control through the discovery of the ætiology; there is a good deal still unknown about the pathology of malaria, and an immense amount remains to be discovered about the deficiency diseases. And if pathology is to progress in its understanding of the anatomy and physiology of disease it must draw its data from the widest sources. Like any other science standing on its own legs, it is concerned to discover the general rules which govern the reactions of live organisms to disease. Substantial progress has been made from an almost exclusively human standpoint; it is plain that this is reaching its limits of fruitfulness. And it is encouraging to see that the necessity for a wider outlook is being realised in various directions. We have a movement for the more accurate study of animal diseases of economic importance; the Royal Society of Medicine has established an appropriate section. Dr. Herbert Fox has published a book about his experience of disease in the wild animals at the gardens in Philadelphia. Prof. Theobald Smith[1] lately addressed an audience in Edinburgh on the import of comparative pathology with the breadth of view which one would expect from his achievements in philosophical bacteriology. Distemper is being taken seriously in hand, some say because of the probable importance of the results when they are applied to analogous human diseases, some say because we are a decent people and love our dogs as well as ourselves. What excuse is given for the pursuit of this particular piece of information does not perhaps matter very much; if there were no analogous diseases in man, and if we took a Frenchman's view of the dog, distemper would still be worth finding out about, and we hope the money will be forthcoming to finance a worthy inquiry. Perhaps, too, the proceeds of the new aquaria in Regent's Park may enable the Zoological Society to make a more extensive provision for the application of the modern methods of a medical school and hospital to the animals under their care. Comparative pathology has waited a long time; it seems likely that by one route and another more rapid progress will soon be made along the path indicated by Hunter, James Paget, and William McEwen.

GENESIS OF MINERS' NYSTAGMUS.

Dr. F. Robson's theory of the genesis of coal-miners' nystagmus—that the main factor in its causation is not defective light, but some gaseous emanation from the coal itself, probably carbon monoxide—was set out in our columns after he had read his paper to the South Wales Institute of Engineers a year ago.[2] The paper is now republished in book form,[3] together with the discussion to which it gave rise, generally, it must be admitted, not very favourable to the author's views, though they are by no means without support, both medical and lay. The subject is such an important one from the economic point of view that it is a matter of regret that medical opinion respecting it is even now by no means unanimous. The data on which theories have been formed are mainly statistical, depending on the number of cases of nystagmus in miners which obtain compensation under different conditions and in different areas. These statistics, as has been pointed out by several of those who have taken part in discussions on the subject, are liable to several fallacies. One is the definition of the disease. In ordinary medical parlance nystagmus means an involuntary oscillation of the eye-balls. It is found that a considerable percentage of miners, after a certain number of years' work at the coal face, are subject to this malady. Only a small proportion of these, however, complain of any unpleasant or disabling symptoms. When the question of compensation comes in, the number of those claiming it is said to depend largely on the amount of compensation obtainable and its relation to wages, and as neither of these factors have been by any means constant, we see at once that there must be a material source of fallacy in figures derived from compensation statistics alone. A further source of fallacy is that along with actual oscillation of the eye-balls a number of neurasthenic symptoms frequently occur. By some these are looked upon as an essential part of the disease, by others as a separate entity. In the schedule of 1913 cases of so-called miners' nystagmus were admitted for compensation even in the absence of any oscillation of the eye-balls. The subject is further complicated by the fact that the development of miners' nystagmus almost always takes many years even under the most unfavourable conditions, and by the further fact that once a miner has developed it he is very apt to suffer a relapse on returning to work after an apparent cure. Any statistical argument should take all these factors into account, besides the factor of cramped posture, which is still believed to be important by some, the factor of noxious gases which Dr. Robson is chiefly concerned with, and the factor of deficient illumination which his book cannot by any means be considered to have effectually disposed of.

THE DEMONSTRATION OF S. PALLIDA IN TISSUES.

A SIMPLE and remarkably expeditious method of demonstrating the *Spirochæta pallida* in tissues has been devised by Dr. Walther Kranz,[1] of the skin department of the University of Cologne. The method is a modification of the well-known procedure of Levaditi, over which, however, it has important advantages; these depend upon the fact that impregnation with the silver nitrate is carried out in the sections and not in the uncut tissue. This renders the impregnation much more certain, and also allows of a reduction in the time allotted to this step. The method is applicable to either frozen or paraffin sections; the material must, of course, be formalin fixed. In working with frozen sections Dr. Kranz first washes in distilled water and then carries a number of the sections up to 15 into a 0·1 per cent. solution of silver nitrate in distilled water, contained in test-tubes; in this they are left in the paraffin oven for from 4 to 24 hours. They are then washed in distilled water and carried over into a solution consisting of pyrogallol, 0·2 g.; aq. dist., 15 c.cm.; and mucilage of gum-arabic, 5 c.cm. The reduction of the silver nitrate takes from 30 to 60 minutes, and should be controlled under the microscope; when it is complete the sections are washed in running water to free them from the gum, carried through alcohol and xylol, and mounted in the usual way. In dealing with paraffin material the sections are first fixed to the slide and freed from paraffin, and then taken through the solutions as described above. No counterstain is necessary, and the picture is that of a Levaditi preparation. As is evident from the above, the whole procedure can readily be carried through within the period of an ordinary working day, and should prove of great use to workers on syphilitic material.

CUTIS VERTICIS GYRATA.

UNDER this denomination Unna described a condition characterised by irregularity of the surface of the hairy scalp over the sinciput and contiguous parts, with the formation of swellings separated one from the other by sulci which resemble the appearance of the cerebral convolutions. For the most part these swellings are placed in lines radiating from the vertex, somewhat undulating, and of a breadth varying from 2–3 cm. and from 10–15 cm. in length. Their surface is convex in the direction of their width. More rarely the lines are arranged in parallel fashion with regard to the sinciput. The swellings and the sulci are much more marked near the vertex. Andry described a similar condition under the name "Pachyderme vorticillée du cuir chevelu," and Calle under the name "Cuir chevelu encephaloide." It was Jadassohn who first drew attention to this condition at the Ninth Congress of Dermatology held at Berne in 1906, and the following year Unna published three cases in which he attributed the condition to a disproportion between the dimensions of the skull and those of the skin which had become exuberant owing to a kind of hyperplasia of its superficial parts. Dr. Benedetto Sparacio, of the Dermatological Clinic in the University of Rome, has lately published another case of this rare and interesting condition.[1]

[3] Coal-Miners' Nystagmus. By Frederick Robson, M.D. Reprinted from the Proceedings of the South Wales Institute of Engineers. Published by the Institute, Park-place, Cardiff, 1924. Vol. xxxix., Nos. 2 and 4. Pp. 556. 10*s.* 6*d.*

[1] Münch. med. Woch., May 9th, 1924, p. 608.

The patient was a woman, aged 53, who, early in November, 1922, began to suffer from excoriations on the tongue, pharynx and mucous membrane of the cheeks, lips and nose. About two months later bullæ appeared on the shoulders and other parts of the skin. In April, 1923, she was admitted to the clinic and noticed to be suffering from pemphigus, and as she complained of itching of the scalp the hair was cut and numerous bullæ were found there. About five months later when the hair was cut again the hairy scalp was seen to have developed the condition known as "cutis verticis gyrata." The changes which occupied all the hairy scalp except those parts corresponding to the lower third of the temporal bones, the middle third of the occipital, and lower part of the frontal were much more marked over the vertex. Over these areas there were swellings separated by sulci of a depth of 3–4 mm. Not all the sulci were of the same depth or length, and in some parts they were hardly noticeable. One small sulcus in the right temporo-parietal region, which measured 3 cm. in depth, was observed during the space of a month to have become much deeper and longer. Over the whole area about 31 sulci were counted. The development of the hairs were normal; those which grew on the edges of the sulci were intertwined, giving the appearance of a brush. The entire scalp was freely movable over the skull. A histological examination was made possible owing to the death of the patient, and the sections showed that in the parts corresponding to the sulci every trace of these had disappeared so that the sections presented a plain surface, while, on the other hand, the lower epicranial superficies appeared undulating and indented, corresponding to the *retinacula cutis.* The only histological change noticed was a slight inflammatory condition represented by a small-celled infiltration of the papillary bodies and the superficial layer of the derma. There were no changes in the middle and deep layers, nor in the vessels, sweat glands, or sebaceous follicles.

In view of these histological observations, the presence of the sulci noticed during life cannot be attributed to cicatricial retraction, nor to hyperplasia of the connective tissue, nor to a condition of elephantiasis of the derma causing the brain-like swellings, explanations given by such observers as Verres, Vignolo-Lutati, and Pasini; any nævoid change must also be excluded. When the disappearance of the swellings and sulci post mortem, together with the normal structure of the scalp, is taken into consideration with the appearance of the undulations observed on the deeper layer in relation to the epicranial aponeurosis, it is difficult to avoid the conclusion that in this case the cutis verticis gyrata was caused by a temporary condition of the skin referable to the epicranial aponeurosis and retinacula, analogous in certain respects to that which takes place in the frontal region when the brow is wrinkled by contraction of the frontal muscles. The brain-like swellings may reasonably be attributed also to a condition of œdematous turgescence which disappeared post mortem contained between rigid and non-infiltrable zones such as those corresponding to the retinacula; the histological examination does not negative such a supposition. The pathology of cutis verticis gyrata may be summed up as a special condition consequent on an inflammatory process, perhaps more dynamic than static, determined by the relations between the superficial fascia, epicranial aponeurosis, and retinacula cutis.

THE summer session of the General Medical Council opened on Tuesday, May 27th, Sir Donald MacAlister presiding (see p. 1132).

THE house and library of the Royal Society of Medicine will be closed from Saturday, June 7th, to Monday, June 9th, both days inclusive.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LXXIII.—TREATMENT OF FRACTURES OF THE ANKLE.

FRACTURES in the region of the ankle include Pott's fracture and its converse, fracture of one or of both malleoli; and fracture of the posterior margin of the articular surface of the tibia, in association with posterior dislocation of the ankle. Variations of the more typical fractures are constantly met with.

Relation of these Fractures to the Function of the Foot.

Fractures of the ankle are important mainly in so far as they affect the chief function of the foot and ankle, that of bearing the weight of the body and of propelling it. Recovery of this function is the chief object of treatment, though for cosmetic reasons also correction of displacement is desirable. If the posterior displacement of the foot is not corrected, it means that the patient will be unable to dorsiflex the foot and so will lose one of the most important movements necessary in walking; indeed, this movement is essential if the patient is not to walk with a limp. If the displacement of the foot laterally—in the case of Pott's fracture—is not corrected, a condition of painful traumatic flat-foot results. The arches of the foot are not rigid but plastic structures, and their support is dependent upon a balanced action of certain muscle-groups. This balance is disturbed by any alteration in the normal line of weight-bearing. Angular deformity, which alters the horizontal axis of the ankle-joint, is associated with the worst kind of functional disability. It is to be noted, therefore, that in all these fractures the position of the foot in relation to the leg must be corrected in both the sagittal and coronal planes.

Details of Management.

Antero-posterior and lateral radiograms of the foot and ankle should be taken. If displacement is present, it should be reduced under a general anæsthetic. The temptation in many of these cases is to put the limb up in such an apparatus as a box-splint and to expect the splint, aided by massage, to do the work of reduction, thus avoiding the necessity of an anæsthetic. Such a policy cannot be too strongly condemned, as it is just here that a little want of resolution is paid for in a poor functional result. Under the anæsthetic it is surprising how easy it is to secure complete and accurate reduction. Special splints have been devised from time to time for controlling a tendency either to backward or lateral displacement of the foot, but for efficiency a plaster-of-Paris casing is much to be preferred. It offers many advantages. It controls displacement in both planes and once applied there is no need for constant attention and readjustment. If applied with care, there is no real fear of interference with the circulation or of pressure sores. It is such fears, which have really very little to support them, that have prevented the more general employment of the very best means at our disposal for securing fixation in many fractures.

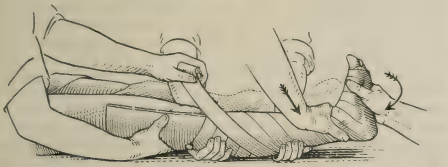
Reduction and Application of Plaster.

In a Pott's fracture, with displacement, the surgeon faces the sole of the foot. In a fracture of the left leg, he grasps the leg below its middle with the left hand. With the right hand he grasps the foot, and corrects the backward displacement by pressing downwards with the left hand and lifting the foot forwards with the right. The lateral displacement of the foot is then corrected by strongly adducting it; in other words, the foot is flexed towards the medial malleolus (Fig. 1). At the same time it is dorsiflexed to a position of 5° or more beyond the right angle. An assistant then powders the skin and envelops the limb from toes to mid-thigh in woollen bandages. A plaster-of-Paris splint is then made for fitment along the posterior aspect of the limb. A plaster bandage, six inches or so in breadth, is placed in a bucket of warm water. The excess of water is gently expressed, and the bandage unrolled backwards and forwards upon itself in re-duplications about two feet long. Each fold is rubbed rapidly into the one preceding, by the flat of the hand, until the bandage is exhausted. In this way a soft pliable splint is available. It is then carefully applied and moulded to the posterior aspect of the leg and sole by the assistant. The surgeon maintains the reduction while this is being done, and finally insinuates his fingers and grasp round the soft splint also. In point of fact this is not difficult, and should any displacement occur it may be corrected at once on the splint. Both leg and splint now being held securely by the surgeon, the assistant applies a plaster-of-Paris bandage round the leg and splint from the toes to the mid-thigh (Fig. 1). This bandage is applied evenly and without such undue pressure as would tend to constrict the limb in any way. A third and fourth bandage are then employed to cover the same ground as the first, and so the plaster-casing is completed. Just as the plaster is setting, the surgeon may make a final adjustment to secure dorsiflexion of the foot and then moulds the plaster in the sole to support the arches of the foot. When set, the plaster is trimmed by a strong knife to expose all the toes. In this way a watch may be kept upon the integrity of the circulation. The majority of fractures of the ankle have not been associated, in my experience, with gross swelling such as text-books often describe. It is a good plan, however, to bi-valve the cast at once into two equal portions by cutting it longitudinally down both sides. Next day radiograms are taken to see that reduction is complete.

---

[1] La Riforma Medica, xl., April 14th, 1924.

FIG. 1.



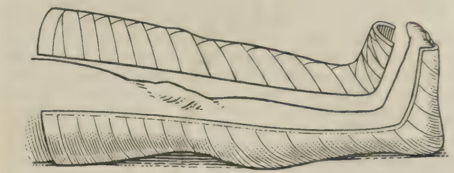
Fixing gutter-splint to limb by application of plaster bandage. The surgeon (on whose arms the arrows are placed) maintains the reduction while the assistant applies the bandage. A second helper supports the limb in the manner indicated.

After-care.

On the day after reduction and fixation the top half of the casing is lifted off and massage begun as the limb lies in the posterior shell (Fig. 2). The full therapeutic effect of massage is secured in this way, and it is not necessary to lift the limb out of the casing until the end of ten days or a fortnight. Massage may be given twice daily, the two portions of the cast being retained in position by a roller bandage. Active movement of the toes is encouraged at once, and when the time comes for lifting the limb out of the casing daily for massage, active and passive movements of the ankle are begun. Opportunity is taken meanwhile to alter the heel of the boot by prolonging its inner half forward for ½ inch and to introduce a wedge of leather, ¼ inch thick, to raise the front inner corner of the heel. Such an alteration helps to support the arch of the foot when weight-bearing is begun. In eight weeks the patient may put on his boot and start partial weight-bearing with the aid of crutches. Indication that full weight-bearing is possible is to be obtained by testing the site of fracture for local tenderness on pressure. If tenderness is present it means that the callus has not completely consolidated and further protection is necessary. In these cases such protection is afforded by the employment of a short iron along the outer side of the leg, let into a slot in the heel at one end and retained around the leg below the knee by a broad leather cuff. It is used in association with an inside T-strap of leather round the ankle.

An alternative plan is to support the ankle and foot by a "stirrup-strapping." Four strips of adhesive strapping, 2 feet long and 1 inch broad, are cut. The patient is instructed to hold the foot dorsiflexed and inverted, while the surgeon applies the first strip from the middle of the outer aspect of the leg downwards over the lateral malleolus across the sole and up the inner surface of the leg. The other strips are then applied in the same way in an imbricated fashion and bound down to the front of the leg and ankle by short cross-pieces of adhesive plaster. A narrow domette bandage is then put on neatly over all, and in this way an excellent ambulatory splint is obtained.

FIG. 2.



Bisected case: showing plaster-of-Paris splint divided into anterior and posterior halves for exposure of the limb. Note the dorsiflexed and inverted position of the foot.

For other fractures in the region of the ankle the same methods are employed.

Fundamental Rules.

The principles followed may be formulated in the following fundamental rules:—

(1) Complete anatomic reposition should be the goal in all cases.

(2) When displacement is present, the plan of treatment should be reduction under an anæsthetic followed by immobilisation in a plaster-of-Paris casing.

(3) When rigid dressings are applied care should be taken to fix the foot and ankle in the position of optimum function—that is, with the foot at or beyond right-angle dorsiflexion, the foot inverted and the arches supported.

(4) The fundamental supporting structures of the foot being largely muscular, their tone and strength must be preserved by beginning massage and active movements at as early a date as possible.

(5) When weight-bearing is first permitted, the foot being weak, support should be given by the use of a heel whose inner border is prolonged forwards and elevated.

W. A. COCHRANE, F.R.C.S. Edin.,
University Tutor in Clinical Surgery, University of Edinburgh.

BRISTOL ROYAL INFIRMARY. — At the annual meeting of the governors of the infirmary on May 21st, Lieut.-Colonel P. G. Robinson, President, in the chair, the annual report showed that the year 1923 had been one of progress. An up-to-date department for dental patients was opened during that year and the number of dental patients had been doubled. In the wards and out-door departments of the institution 61,500 patients had been treated, a number which was equal to one-sixth of the population of Bristol. A large amount of work had also been done in the maternity department and in the children's wards. Reference was made to the bequests of the late Mr. H. H. Wills, who, in addition to a sum of £11,250, had given the infirmary 21,000 ordinary shares in the Imperial Tobacco Company (of Great Britain and Ireland), Ltd. The total value of Mr. Wills's bequests amounted to date to £83,700. Unfortunately, there was a deficit of £4000 on the year's working of the infirmary, but this, it is hoped, will not interfere with the opening of new wards as soon as increased nursing accommodation is provided.

Special Articles.

THE PEOPLE'S LEAGUE OF HEALTH.

FIRST INTERNATIONAL CONGRESS AT WEMBLEY.

THIS congress was opened by Viscount Burnham, the President, at Wembley on May 21st. The President said that the League had done much pioneer work in educating the public as to health matters. Much of the success of Public Health Acts depended upon the support of public opinion. When in Jamaica last year he saw how much the officers of public health were hampered and obstructed by the apathy and ignorance of the multitude. Great things had, however, already been done in combating tropical diseases.

The Housing Section.

Mr. Neville Chamberlain, M.P., who presided over the Housing Section, also pointed out that progress in public health depended upon public opinion. All Governments in this country followed, but did not lead. Housing was a problem of old countries and especially of the industrial towns of old countries. It was a legacy from the population of 100 years ago who built houses according to the standard of that time. It was a pity no one had yet invented paper houses. Houses were at present built to last 80 years, and would be out of date long before that time. It was not only rehousing that was necessary, but redistribution of the population. The housing question therefore was bound up intimately with the transport system, and housing reformers needed to exercise much forethought.

Mr. James Stewart (Parliamentary Under-Secretary for Health in Scotland), referring to the paper houses described in Bellamy's "Looking Backward," said that 80 years was much too long a life for a house. His experience of wooden houses in America was that they were quite warm and comfortable. He agreed with Mr. Chamberlain that the housing problem was not entirely the result of the capitalist system, but that it was rather due to the general ignorance of our forefathers. For instance, the homes of the aristocracy which had been converted into Government offices were wanting in light and air. Money spent in housing would bring a return, but rather resembled capital invested in commercial enterprise, which did not earn dividends at once. As a native of Glasgow he was appalled by the percentages of the population living in homes of one and two rooms respectively. He believed that much of the tuberculosis in Glasgow was due to housing conditions. £220,000 a year were spent in efforts to cure tuberculosis—mostly futile. Better housing would not only mean less tuberculosis, but less expenditure on widows and orphans, on the sick poor, on voluntary hospitals, and on the results of crime and intemperance. Housing had become the sport of politicians. There should be a whole-hearted effort of all parties to find a remedy. He agreed with Mr. Chamberlain that redistribution was necessary. He hoped for smaller towns and cities. The intelligent use of electric power would help in this direction. If we did not solve the housing problem we were doomed as a nation.

Dr. John Robertson (M.O.H., Birmingham) said that many English towns had the evils of back-to-back houses to put against the tenements of Glasgow. The back-to-back houses were mostly three-roomed and *did* allow the children to get out, and for that reason were infinitely preferable to the Glasgow flat system. He was hopeful about town-planning, but urged that if town-planning were to be successful provision must be made for the recreation of the population at every age. If the number of houses per acre were limited there would be open-air space for the baby and the toddler in the garden under the eye of the mother. Small school-children needed playgrounds near their homes. For children from 8 to 10 years special accommodation was needed in the parks; from 11 to 12 playing fields; from 14 onwards larger playing fields. After 25 recreation could usually be paid for. Allotments were essential, and at present were too far from the homes and were held on too precarious a tenure. No town in the country had yet made adequate provision for the recreation of its population. He estimated that eight acres were needed per thousand of the population: five for games, two for allotments, and one for parks for the elders. This open space might in the future be provided on each side of the main arterial roads, which the noise of the traffic would render unsuitable for housing sites.

Dr. F. E. Wynne (M.O.H., Sheffield) said that housing had become such a burden on rates and taxes that local authorities had been obliged to select good tenants. This was wrong. The evacuation of slums should be the first charge on housing. Sickness and disability caused by bad housing cost more than the subsidies to housing. There was no difficulty in showing that the bad conditions in the slums caused high death- and disease-rates. An area in Sheffield which was condemned by Dr. Robertson had not been dealt with yet. He thought this was not a time for rigid adherence to ideals and that every housing scheme should include some very cheap temporary houses. It was true that the tenants from the old slums might make these into new slums, but he thought this could be prevented by a combination of firm administration and Octavia Hill methods.

Dr. Leonard Hill pleaded for greater simplicity in houses. As long as one got plenty of open air and sunshine the house was a matter of little importance. The new houses were already out of date according to modern hygiene. He suggested that the local authority should secure areas and allow persons who wanted houses to erect their own free of any restriction. The local authority would only need to provide pure water and arrange for the careful disposal of the sewage and excreta.

Food Section.

Sir W. Arbuthnot Lane, in opening the proceedings of the Food Section, said that he would like to see the food experts present at the congress arrange a dietary which would give rise to three or four motions in the 24 hours. The baby, during its napkin stage, was the only member of our community sensibly treated. After babyhood a system of regulated constipation was taught.

Prof. E. Mellanby pointed out that practically every child of 5 had decayed teeth and that rickets was a very common disease. Cereals were the chief cause and oatmeal was the worst cereal. We must eat cereals, but fortunately we were able to antagonise the bad effects of the cereals by an adequate supply of foods containing the fat-soluble A-vitamin. Cod-liver oil was the best source of this vitamin and milk had a better effect than butter. Sunshine in virtue of the ultra-violet rays would also antagonise the bad effects of cereals, but was not efficacious if the diet were very bad. A small daily dose of cod-liver oil was beneficial during the winter when sunshine was scarce.

Prof. R. H. A. Plimmer dealt with the various kinds of protein. He explained why one protein was more valuable than another in promoting growth and nutrition. The protein of cereals alone was not sufficient, but the protein of cereals and green-leaved vegetables combined might suffice for a strict vegetarian.

Prof. J. C. Drummond dealt with the great value of milk as a food. He instanced the bad effects of the scarcity of milk on the children of Central Europe, and the wonderfully good results obtained by providing ill-nourished school-children in America with an extra pint of milk per day. The experiments in America were being continued, but up to now it appeared that the improvement produced by the milk was out of all proportion to its caloric value and was probably attributable to the vitamin-content of the milk. Research was now in progress as to the effects of pasteurisation and desiccation on milk, and up to the present it would appear that the food value of these forms of milk, if properly prepared, was much the same as that of untreated milk.

As the result of the discussion which followed the reading of the papers, a resolution was adopted requesting the Council of the People's League of Health to appoint a special committee to draw up for popular use a pamphlet of instructions as to the dietary necessary to promote good nutrition and health.

Air, Light, and Water.

The second day's proceedings of the congress were of equal interest. In the morning the members listened to an exposition of the latest views as to the value of light and air by well-known authorities under the presidency of Sir Henry Gauvain. Dr. Fortescue Fox put in a plea for the systematic study and organisation of British spa treatment, and instanced the value of such treatment for chronic rheumatism and breakdown in middle life. The chief event of this section was Dr. A. Rollier's fascinating and suggestive paper on the rôle of the sun. The paper described the methods adopted at Leysin, their preventive application to debilitated children in the "Sun" School at Cergnat, and the possibilities of applying these principles in everyday life; and was illustrated by lantern slides showing the wonderful results obtained in the treatment of tuberculous cripples.

Some Overseas and Other Diseases.

Sir Leonard Rogers dealt with leprosy. There were probably more than 2,000,000 lepers in the world. In spite of the success of modern treatment by chaulmoogra oil, he estimated that only one-tenth of the lepers in British Dominions were receiving treatment. Segregation had not been applied scientifically and perhaps 75 per cent. of the lepers at present segregated were non-infectious.

Dr. George Low, in discussing filariasis, showed that the mosquito (*Culex fatigans*), which acted as the intermediate host of the causal worm, was more easily extirpated than the malaria mosquito. *Culex fatigans*, like stegomyia, the vector of yellow fever, had domestic habits and was found in water-barrels, &c., near dwellings. In the West Indies both these mosquitoes were tackled simultaneously. In many British colonies anti-mosquito measures were still not conducted with sufficient energy.

Dr. P. H. Manson-Bahr described the modern usage of antimony preparations, arsenical derivatives, bismuth, quinine, Bayer "205," and emetine in the treatment of kala-azar, bilharziasis, trypanosomiasis, yaws, malaria, dysentery, liver abscess, and other tropical scourges.

Dr. Andrew Balfour wound up with a paper on vermin and their relation to disease, using the term "vermin" in a wide sense. It may be confidently said that, at the close of the session, none of the audience disagreed with Dr. Balfour's pronouncement that our efforts to destroy vermin are too half-hearted, and that our interest in the promotion of research is altogether inadequate when compared with the greatness of our responsibility.

Mental Hygiene.

At the morning session of May 23rd the Conference settled down to discuss the hygiene of the mind, under the presidency of Sir Courtauld Thomson.

Dr. Farquhar Buzzard insisted that the term "nerves" must go. It was a term invented for our deception because we did not like talking about our minds. Medical opinion was unanimous that hope for future improvement lay in the prevention and early detection of disorders of function. Why should a man confess without a blush to having a disorder of the liver, perhaps the result of over-eating or over-drinking, and his brother be afraid to admit a disorder of the mind, caused by overwork or anxiety. If the term "nerves" were abolished and the prejudice about the use of the word "mental" disappeared, they would have taken the biggest step forward in the promotion of mental hygiene.

Sir Frederick Mott strongly advocated the establishment throughout the country of more hospitals like the Maudsley, and pointed out that the study and treatment of early cases would be much more useful if the law could be so altered that patients could be detained for more than 24 hours, even against their wish.

Dr. H. Crichton Miller said there was no hard-and-fast differentiation between sane and insane. Some asylum cases are curable, many uncertified cases of mental breakdown can be saved, and a very great proportion of both might be prevented. Much research is still called for, but much of our present knowledge is not applied, partly because public opinion is not educated and partly because the necessary funds are not available. We need greatly increased personnel in our asylums, more research into individual cases, and more chairs in our mental schools which will attract the best brains in the alienist world. Perhaps more important still we need conditions for the treatment of minor mental disorders which will secure the coördination of specialised medical skill for individual cases. Such a vision needed great financial support.

Dr. R. G. Rows said the recognition of the fact that the delinquent was made, not born, would put an end to the feeling of helplessness and hopelessness and justify the hope that change of environment and education of parents and child would do much to prevent delinquency.

On the following day Prof. George M. Robertson contributed an interesting paper on the Hospitalisation of the Asylum, and confirmed the views of other speakers as to the need for an increased medical staff in asylums, more research, and more careful study of individual cases. He advocated several changes calculated to make asylums more like hospitals, such as the admission of all voluntary cases, whether they can pay or not, the temporary notification of cases by two medical men in lieu of certification, and the more frequent revision of legally detained cases.

Industrial Hygiene.

At the afternoon session of May 23rd the hygiene of industry was considered. Sir Thomas Oliver presided, and the speakers included Prof. E. L. Collis, Dr. C. S. Myers, Director of the National Institute of Industrial Psychology, and Dr. F. Shufflebotham.

Dr. Myers pointed out that industrial psychology is concerned in alleviating the strain arising from defective arrangements of hours of work and rest, or from rare or too frequent changes of work; from waste of energy due to unsystematic training, unnecessary and unrhythmical movements, needless standing and stooping, &c.; from inefficient illumination, excessive vibration, humidity and temperature, &c.; and from unfitness for the occupation adopted. The hygienic value of industrial psychology was clearly reflected in the diminished sickness records, the increased output, and the greater happiness of the workers, obtained by its application.

In his paper on lead poisoning among pottery workers Dr. Shufflebotham pointed out that acute cases of lead poisoning had been wiped out by the Home Office regulations, but that chronic cases still occurred and were very unfairly treated under the Workmen's Compensation Act. The monthly examinations by the factory surgeons had acted beneficially to leadworkers, but the power to suspend workers who might have been engaged in this occupation for 30 or 40 years, presumably because they were suffering from lead poisoning, was a manifest injustice.

Dr. Ralph C. Matson, Director of the National Tuberculosis Association, U.S.A., described a typical American intensive health experiment, by means of which the population of Framingham, Massachusetts, numbering 17,000, had been provided, after a study of the conditions, with an up-to-date organisation, where practically none existed before, to the great benefit of the residents and industrial workers, and with a lowering of 16 per cent. in the general death-rate and about 50 per cent. in the mortality from tuberculosis and among infants.

Legislation on Health Matters.

Lines of progress for the future and desirable legislative changes were the theme for the last session on Saturday, May 24th, Miss Margaret Bondfield, M.P., presiding. In opening the session Miss Bondfield said that although legislative changes must come they would have little effect in raising the standard of health unless the people were roused to the importance of obeying the laws and seeing that they were strictly administered. No matter what the legislative changes, there would always be room for voluntary effort. Amongst the legislative changes required were amendments of the Midwives Act, powers for the registration and inspection of maternity homes, and power for the compulsory removal to hospital of persons who were a danger to others. Referring to the House of Commons debate on the maintenance of the blind, Miss Bondfield said more could be done at childbirth and in early infancy to prevent blindness —a much more sensible policy.

Prof. W. E. Dixon made out a strong case for the standardisation of drugs.

Dr. C. J. Bond pressed the need for an institutional branch of a unified health service, coördinating the work of all institutions dealing with both mind and body. He wanted State aid in such a way as to retain the present voluntary and local management. The interests of the Ministries of Education and Health should be fused, the teaching of personal, sex, and social hygiene should become part of our educational system, and the Ministries of Health and Education should coöperate to secure the education of exceptional children.

Dr. F. E. Fremantle, M.P., emphasised the rôle of the individual. Voluntary effort should be encouraged on insurance principles. Laws should be so supple as not to stifle voluntary help and effort.

Resolutions.

Resolutions were passed in favour of :—

1. Establishment of an adequate hospital and institutional service instead of the present partial and incoördinated service, so frequently curtailed by lack of funds.
2. Action to be taken by the Ministry of Health with regard to the supply of wholemeal or standard bread and the education of the public as to the disadvantages of bread made from highly refined flour.
3. Prohibition of the unnecessary addition of preservatives to food.
4. Need for the extension of legislative control to infant foods consisting partly or mainly of starch.
5. Powers for the protection of children from the infection of advanced cases of tuberculosis, either by the removal of the children or of the infecting case from the home.

The Conference terminated with votes of thanks to all who had helped to promote its success. Miss Olga Nethersole is certainly to be congratulated in having assembled a large body of medical speakers, each eminent in his own particular line. The proceedings of the Conference will be published in book form in order to reach a wider circle.

SOUTH LONDON HOSPITAL FOR WOMEN. — On May 22nd the new wing of the hospital at South Side, Clapham Common, was opened by the Duchess of York. The Mayor of Wandsworth referred to the hospital, which was opened by the Queen in 1916, as an example of the efficacy of women's work and paid a special tribute to Lady Cowdray's full-hearted support as its chairman. Upwards of 50 purses, containing a total of some £1100, were presented to the Duchess of York by representative bodies and citizens of South London towards the cost of the new wing which has been furnished throughout, including theatre equipment, by an anonymous donor. The wing provides accommodation for 38 additional patients and is expected to lessen substantially the waiting list, on which at present some 600 names stand. To defray the cost of the necessary building alterations another £6000 are needed.

THE DIFFICULTIES OF INSURANCE PRACTICE.

THREE OFFICIAL INQUIRIES.

WE print below summaries of the reports of three Inquiry Committees appointed by the Minister of Health since the beginning of the year. Each committee was appointed to investigate a representation made by an Insurance Committee that the continuance on the panel of an insurance doctor would be prejudicial to the efficiency of the medical service of the insured.

The facts only are summarised which the Inquiry Committee found to be proved by the evidence submitted to them. The decision given by the Minister after considering the report of the Committee is appended to each case.

I.—*Inadequate Deputising Arrangements: Irregular Certification.*

Members of the Committee: Mr. E. H. Tindal Atkinson, C.B.E., Barrister-at-Law (Chairman), Dr. J. Divine, Dr. Alex Forbes.

The doctor had been in insurance practice since 1912 ; for several years he had practised in a town with a population of 44,000. He had over 1600 insured persons on his list. He had two consulting rooms, one at his own residence and one at a neighbouring smaller town.

With regard to the specific charges made in the representation of the Insurance Committee, the Inquiry Committee found the following facts to be proved :—

1. The doctor left home on August 4th for a short holiday, returning on the 9th. During his absence his house and consulting rooms were closed and no arrangements were made with any other doctor for the treatment of his insured patients. The local medical officer of health, Dr. A. B., had consented at the doctor's request to attend two of his patients (one of whom was an insured person), but had not been asked to exercise any general supervision over the needs of the insured patients, neither could he have done so owing to his public duties. The Insurance Committee received no complaints from any insured persons as to want of attention during the doctor's absence.

At the hearing the doctor produced a notice which stated that he was absent until August 9th, and that cases of emergency could be referred to Dr. A. B. or to another doctor. This notice, he stated, was affixed to the door of the consulting room during his absence, but the Insurance Committee contended that this notice had never been exhibited.

2. Before going on his holiday the doctor signed intermediate certificates for eight insured persons on his list, the certificate in each case stating that he had examined the patient on a date when he was, in fact, away. The causes of incapacity were mostly ailments involving some probability of continuance. On his return the doctor issued a first certificate to an insured person, antedating it one day before his return.

3. The doctor had also issued insurance prescriptions to 16 persons not on his list ; two of these were cases of urgency not admitting of inquiry, and in the other cases there had been some mistake as to names, initials, or identity. The doctor also issued prescriptions to three persons who were on his dispensing list, and in one case he issued 14 post-dated prescriptions to a patient resident two miles from his house.

4. The doctor's wife owned shop premises adjoining the doctor's residence, which were let to an insurance chemist, C. D. A disagreement, which developed into a personal quarrel, arose between the doctor and the chemist in connexion with the renewal of the tenancy. After the date of the notice to

terminate the tenancy the chemist noticed a marked falling off in the number of insurance prescriptions brought to him. The doctor admitted that where insured persons asked his advice as to the choice of chemist he gave it to them, and it did not seem to be disputed that in such cases he had advised them to go to some chemist other than C. D.

The Inquiry Committee drew the following inferences from these facts :—

(1) In leaving for his holiday as he did, the doctor committed a breach of the spirit as well as of the letter of Article 10 (2) of the Terms of Service. [Article 11 (2) in the current Regulations of 1924.] They did not accept the doctor's argument that this Article gives the doctor a right to go away for a week without making deputising arrangements ; neither did they accept the doctor's plea that the ordinary provisions for emergency treatment were sufficient to meet any difficulties which might arise.

> "We think on general grounds that no insurance doctor should be recognised as able to leave his practice even for a few days in a kind of pious hope that all will be well and that his brethren will render assistance in cases of emergency. The fact that no person either complained or gave evidence of having suffered inconvenience must be noted in the Respondent's favour, but this does not alter our view as to the standard of conduct which should properly be attributed to an insurance practitioner when taking a holiday and not faced with a sudden and unlooked for emergency. Even if we had come to the conclusion beyond all doubt that the notice produced to us had been exhibited and that Dr. A. B. had given some promise of supervision, we think that an arrangement of this kind, particularly in view of Dr. A. B.'s position, would have been wholly inadequate for securing proper attention and treatment for insured persons."

(2) The Committee considered that the certification irregularities constituted the gravest of the charges. They thus expressed themselves :—

> "We can conceive of no circumstances justifying an insurance doctor signing his name to a false statement that he had examined a patient on a date upon which in fact he had not or could not have done so. In view of the use to which these certificates have to be put and the reliance placed upon them by societies and others, we think it impossible that any latitude can be allowed or any excuse should be admitted for deliberate inaccuracy or falsity, particularly as to the date of examination."

(3) The issue of prescriptions to persons not on his list revealed a considerable amount of carelessness in keeping records, and the writing of prescriptions for patients on his dispensing list showed at least great carelessness. As regards the issue of post-dated prescriptions to one patient the Inquiry Committee stated :—

> "While we think that in particular cases such a course might be justified, we feel some doubt whether in the present case sufficient grounds were shown for issuing these prescriptions in batches whereby the patient was apparently enabled to obtain an unreasonably large quantity of medicine at one time."

(4) On the charge that the doctor had influenced patients in their selection of an insurance chemist, the Inquiry Committee observed :—

> "The Respondent frankly took his stand on the right of an insurance doctor to give advice to, and at the request of, an insured patient as to the choice of a chemist. While there is nothing in the Acts and Regulations directly affecting this point, we think that any conduct likely generally to interfere with the patient's freedom of choice is not desirable, although there may be particular occasions upon which such advice might rightly be given."

The general conclusion on this particular issue was that the doctor had taken too wide a view of his rights to tender advice, and that his behaviour could be called in question "more in relation to a general standard of conduct than to a test as to whether he complied with his terms of service."

Decision.—The Minister decided that the doctor's name should be removed from the Medical List, and that he should pay the costs of the Insurance Committee.

II.—*Neglect of Patient and Failure to Visit : Intoxication : Irregular Certification.*

Members of the Committee : Mr. E. H. Tindal Atkinson, (Chairman), Dr. H. G. Dain, Dr. C. E. S. Flemming.

The inquiry related to a doctor who had for some years been in insurance practice in a town of 1200 inhabitants ; he had 270 insured persons on his list.

The Inquiry Committee found the following facts as proved :—

1. K. L., an insured person on the doctor's list, was taken ill on Sunday. At the request of her husband, the patient's wife sent for the doctor on Monday morning at about 9.30 A.M. The doctor, who lives about a mile away from the patient's house, arrived shortly after 3.30 P.M. The patient was ill in bed and in pain, and the doctor examined his chest, took his temperature, which was about 104°, and gave him a prescription and a first certificate stating that the patient was suffering from influenza. The doctor's hand was not steady when he took the patient's temperature and wrote the certificate, and he smelt of drink. The doctor did not visit the patient on the next day, but called again on Wednesday, shortly after 3.30 P.M., when the patient's wife complained of his not coming before. The doctor examined the patient whose condition had not improved, took his temperature, which was 104°, and administered a soap enema. The doctor's hand was unsteady and he smelt of drink. After his examination the doctor informed the patient's wife that her husband was very seriously ill, that he would probably not recover, and that it would be advisable for her to send for any relations who might wish to come upon an emergency of the kind. The doctor appeared to the patient's wife to be under the influence of drink both from his manner of speech and from the way in which he walked.

The Inquiry Committee came to the conclusion that while, on both these occasions, the doctor was capable of carrying on a simple and ordinary examination or of giving an ordinary prescription, "he was so far under the influence of drink that his power of judgment and sense of responsibility were affected, and, moreover, affected to a degree which would render him unfit to be in charge of a serious case of illness."

As the doctor failed to call on Thursday and as the patient was then worse, the patient's wife sent for Dr. M. N., an insurance doctor in a neighbouring area, who discovered that the patient was suffering from pneumonia, and immediately took active steps to treat him for this complaint. Dr. M. N. took a sufficiently serious view of the case to cause him to visit the patient daily for some eight days after this first visit. The patient's own doctor had meanwhile called on Friday and, finding that Dr. M. N. had been called in, he expressed some indignation and left the house.

2. At the request of a friend of the patient and to enable the patient to draw his sickness benefit without delay, the doctor signed a certificate stating that he had examined the patient on a day when the patient was, in fact, only seen by Dr. M. N. The doctor failed to enter on the patient's medical record card the particulars of the illness.

3. While the Inquiry Committee found that, upon the evidence adduced before them, the general charge that the doctor was addicted to excessive drinking was not proved, they found as a fact that on three occasions the doctor had to some degree been under the influence of drink. In 1915, while attending to a difficult maternity case of his own, the doctor had sent for Dr. M. N. to assist him and was on that occasion sufficiently under the influence of drink to deprive him of the confidence necessary for him to undertake the delivery of the child, although he was capable of administering an anæsthetic under Dr. M. N.'s supervision. In 1922, when he had occasion to examine a war pensioner, his hand was very unsteady and he smelt of drink. In 1923,

when appearing at an inquiry before the Medical Service Sub-Committee, the respondent was to some degree under the influence of drink.

The Inquiry Committee drew the following inferences from these facts :—

1. The charge of neglect in the treatment of K. L. was by far the gravest of those preferred ; the doctor was mistaken in not calling on the Tuesday, and he was negligent in not calling on the Thursday, having regard to the opinion expressed to the patient's wife on Wednesday. The Committee did not consider that " he was in the least justified in expecting the patient's wife to undertake the responsibility of relying on her own judgment in the matter as to sending for him."

2. As regards the issue of the irregular certificate,

> " The doctor raised no defence to this charge other than what he did was done in kindness. In our view this raises no defence on the plain issue that an insurance doctor had no right to put his name to a false statement on a certificate which is a document upon which of necessity great reliance has to be placed by societies and others."

3. On the charge that the doctor was addicted to excessive drinking the Inquiry Committee heard considerable evidence—much of it necessarily given in a partisan spirit—and they record that many witnesses expressed their confidence in the doctor as a medical man. The Committee came to the conclusion that the doctor—

> " At times suffers himself to be under the influence of drink in a degree which is unwise, but we do not draw an inference that his lapses in this respect are other than occasional. It is scarcely necessary to point out that even such occasional lapses are to be deplored in the case of any medical man."

They point out that, of the specific cases proved, the first took place eight years ago.

Decision.—The Minister decided that the name of the doctor should be removed from the Medical List and that the doctor should pay the costs of the Insurance Committee.

III.—*Negligent Treatment : Careless Dispensing.*

Members of the Committee : Mr. E. H. Tindal Atkinson, Dr. H. G. Dain, Dr. J. Steed.

The doctor had for some years had a panel practice in a town with a population of 100,000 ; he had 321 insured persons on his list.

The Inquiry Committee found that the following facts were proved with regard to the specific charges contained in the Insurance Committee's representation :—

1. E. F., an insured person on the doctor's list, called at the doctor's surgery in the evening and requested the doctor to examine him as he was suffering from abdominal pains. The doctor did not examine him, but gave him a bottle containing some fluid which was labelled " one tablespoonful every four hours." The bottle was of a kind and shape ordinarily used for liniment and had the words " not to be taken " moulded in the glass. The patient felt doubtful whether a mistake had not been made and returned the same evening to the doctor who gave him an assurance that the medicine was all right. The patient was still not satisfied, and a day or two later he instructed his wife to take the bottle to the clerk of the Insurance Committee, who suggested that she should take it to a local chemist. The latter, discovering that the liquid in the bottle consisted partly of turpentine, gave certain advice to the patient's wife, who thereupon took the bottle back to the Insurance Committee clerk in whose custody (except during a subsequent analysis) it remained until the date of the inquiry. The patient did not, in fact, take any of the contents of the bottle. An analysis showed that about 80 per cent. of the liquid consisted of an aqueous infusion of gentian and about 20 per cent. of turpentine containing resin in solution. The two liquids would not mix, although upon being shaken the turpentine would for a short time take the form of an emulsion in the other liquid. From the medical point of view, the Inquiry Committee state, such a mixture was not suitable for dyspepsia or for any ordinary complaint of the kind from which the patient was apparently suffering.

2. About ten days later the patient, feeling dissatisfied, called on the doctor and requested him to sign a form of transfer to the list of another insurance doctor. The doctor asked for a fee of 6*d*. for the signing of the form ; the patient, not having money with him, did not pay the fee demanded and the transfer form was not signed.

3. G. H., another insured person on the doctor's list, was taken ill with pleurisy and pneumonia. The doctor called to see him on a Thursday and conducted a somewhat cursory examination. The patient's wife sent for the doctor to call on the Friday and herself went to see the doctor on the Saturday, informing him that her husband was seriously ill and raving. The doctor did not call to see the patient on either of these days but promised to send some medicine on the Saturday. The medicine was not sent. A message was sent to the doctor to call on the Sunday ; he could not call on that day because he was himself ill and in bed.

Dr. I. J., another local insurance doctor, was therefore called in on Sunday and attended the patient ; he found that the patient had been suffering from pneumonia, but that his condition was then improving. The patient's own doctor called to see him on the next day, Monday, but the patient's wife refused to allow him to see her husband, informing him that Dr. I. J. was then in charge of the case.

The Inquiry Committee found the following inferences of fact :—

(1) In the case of E. F. the doctor failed to give adequate medical treatment. His actions were criticised under three heads : (*a*) he supplied medicine to a patient whom he knew to be an insured person, for a case that was not one of emergency and at a time when chemists' shops were open and a prescription could have been dispensed ; (*b*) he supplied medicine to be taken in a " poison " bottle ; (*c*) he included turpentine in the mixture which rendered it unsuitable for internal use. The latter two acts, although apparently lacking a deliberate wrong intention, can be attributed only to carelessness for which it is difficult to account. The Inquiry Committee felt bound to draw the inference that the doctor was on this particular occasion not in a fit mental condition to deal with patients at all. In the absence of evidence they did not suggest possible causes for this condition.

(2) The Inquiry Committee considered the doctor's action in demanding a fee for signing the form of transfer was contrary to the spirit of the terms of service ; they were unable to find that the charging of a fee for such a service was definitely prohibited by the Regulations.[1]

(3) The doctor was negligent in not calling to see G. H. on the two days subsequent to his first visit, as this patient was then seriously ill and should not have been left unattended.

The Inquiry Committee called special attention to the conduct of the doctor at the inquiry. Although every effort was made to point out to him the serious nature of the charges brought against him and to invite him to deal with them by the test of cross-examination and by adducing affirmative evidence in his favour, he did not seem capable of appreciating the nature of the inquiry or his position as respondent to these charges, and he did little to furnish any reply by way of defence.

Decision.—The Minister decided that the doctor's name should be removed from the Medical List and that he should pay the costs of the Insurance Committee to an amount not exceeding £20.

---

[1] Since Jan. 1st, 1924, the insured person can change his doctor at any time and the transfer form is, therefore, not now in use.

BRITISH EMPIRE EXHIBITION, WEMBLEY:

ITS MEDICAL AND SANITARY ADMINISTRATION.

"This Exhibition . . . stands for the coördination of our scientific knowledge and a common effort to overcome disease . . . in many parts of the Empire."—H.M. THE KING.

III.

AN important factor in the success of a great undertaking such as a national exhibition is the provision of adequate medical and sanitary services; and at Wembley this is more important than it has been in the case of former exhibitions, owing to the enormous size of the undertaking, and to the fact that there is a very considerable permanent population in the Park largely unused to Western ideas of sanitation.

The medical and sanitary services at Wembley are in themselves well worth bringing forward as features of an all-British exhibition. One of the chief objects of the display at Wembley is to allow every profession and trade a chance of showing its recent march of progress to its lay brethren, and we have at Wembley an opportunity of exhibiting to the public how its health and well-being are cared for in a place where it probably least expects to find such an adjunct to their safety and convenience. The lack of such essential adjuncts in many places where large numbers of people congregate is a sign that those responsible for the management of exhibitions often forget the necessity for any such provision or, at the most, offer it grudgingly and insufficiently. The contrast that Wembley makes with the usual exhibition is in no respect more striking than in the care taken to supply adequate sanitation and medical aid. Both services are remarkably complete and well equipped, and if more descriptive information had been supplied to visitors a very valuable and important exhibit would have resulted—one which would have been highly instructive to many who have little idea what would happen if large crowds are collected together without any precaution being taken against the results of accident or the spread of sickness. Information along these lines may be good seed sown in the minds of many who will at some future time have the responsibility of making arrangements for the organisation of large congresses of all sorts.

The medical staff at the Exhibition consists of the following officers: General Guise-Moores, Director of Medical Services; Dr. C. E. Goddard, medical officer of health; Colonel D. Lawson and Dr. Marjorie Thompson, assistant medical officers.

We are indebted to the Director and the Medical Officer of Health for the information which follows upon the side of the Exhibition under their control.

At numerous places in the grounds, buildings, and amusement park there are first-aid cabinets each in telephonic communication with its affiliated ambulance station, of which there are three. The main station of these is near the south-west entrance to the grounds, and is equipped with 14 beds, eight for women and six for men. This station practically corresponds to a miniature army casualty clearing station, and is connected by telephone with two sub-stations, one of which is situated near the Hong-Kong pavilion and the other near the north entrance to the grounds. None of these posts or stations is marked on the map which is given in the official guide book, and so all are rather difficult to locate.

The motor ambulances are new and of the most modern construction, enabling the transport of the sick or injured to be undertaken with promptness and with all possible regard for the patient's plight. A serious case, which it is not possible to treat at once or continue to treat after first aid in the main ambulance station, is sent to the Willesden General Hospital, where 30 beds have been reserved for the Exhibition authorities. Natives from any of the colonial encampments will be treated at the Seamen's Hospital, Greenwich, where arrangements have been made for the inmates. There is no reason to fear that these extensive facilities for the treatment of sickness will have to be utilised, but it is excellent that the authorities of the Exhibition should not have fallen into the error so common in the past of having to improvise hurried treatment of the sick and measures for the prevention of the spread of disease in the presence of some serious emergency. This is due to the efforts of the Standing Committee held since last October, under the chairmanship of Major-General W. W. O. Beveridge, the Chief Medical Adviser to the Wembley Empire Exhibition and the head of the St. John Ambulance Association and of the Red Cross Society, with the medical officer of health. It should be mentioned here that the St. John's Order and the Red Cross Society have generously provided most of the equipment and personnel, while the Exhibition authorities erected the main station and the north and east stations, and the cabinets.

The sanitary arrangements at Wembley have presented far greater difficulties to the practical sanitarians who have faced them than are suggested by the provision of 15 large lavatories in the grounds, and of several more in the Stadium. One of the most difficult aspects of the matter has been to induce the natives in the various encampments to follow the maxim of "When in Rome do as Rome does." For example, some of the native customs are not intended to be carried out in conjunction with a water-closet system, and tact has been necessary to overcome native prejudices. But the sanitation for a very large number of natives is now running smoothly on Western lines. The natives in addition have their special kitchens and two sanitary inspectors to see after the living quarters and the general sanitation; these inspectors are responsible to the sanitary officer, who in turn reports to the medical officer of health.

For the visitor the accommodation is ample and well fitted, and is supervised by one female and two male inspectors responsible to the sanitary officer. The whole of the drainage is on the water system and the surface drainage is by a separate conduit. To provide for the needs of the Exhibition the Wembley Park sewer had to be enlarged up to a diameter of 5 feet, and a sewage farm at Alperton has been constructed at a cost of £40,000, chiefly, though not exclusively, for the purposes of the Exhibition. Rubbish from the various buildings is placed in bins, which are emptied two or three times a day. It is then sifted and burnt by means of eight incinerators installed in the incinerator house on the south-east side of the Exhibition grounds. Food refuse from the many restaurants is collected between 11 P.M. and 6 A.M. by the Wembley Urban District Council and by them removed from the grounds and destroyed. The water-supply of the Exhibition is from the local mains as well as from a specially built reservoir in the grounds which holds over a million gallons.

A feature of the Exhibition, little advertised and extremely difficult to find, being unmarked on the map as well as being unknown to the guides, is the Welfare Hut or Children's Day Nursery. This most excellent institution is under the charge of Dr. Barry Lambert, director of the Central Council for Infant and Child Welfare, who is assisted by trained nurses and V.A.D. helpers, and also by a kindergarten teacher. The children are received and returned to their parents on a check system, and over 100 children can be taken at a time at a charge of sixpence for four hours. They are fed and looked after, either in the hut or in the surrounding garden, which, though small, is well suited to the purpose. The hut, which is most excellently fitted up, is bright, clean, and airy, and being of comparatively inexpensive build should form a model for similar institutions in many of our holiday resorts, where, during an all too short spell by the sea, mothers and young children often react upon each other to their mutual detriment.

The medical and allied services at Wembley are excellent, the buildings are lofty and not too overcrowded with exhibits, the amusements are nearly all in the open air, and the seating and lavatory accommodation is ample and well fitted. If the sun will only allow the roads and paths to dry and the gardens to flourish Londoners in particular and visitors in general should be able to obtain many hours of healthy pleasure amid agreeable surroundings.

A HEALTH BILL FOR THE IRISH FREE STATE.

(FROM OUR OWN CORRESPONDENT.)

IT is expected that the Committee of Inquiry into National Health Insurance and the public medical services of Ireland generally, promised at the beginning of the year, will shortly be set up. As its terms of reference are said to be comprehensive, it was thought that no health measure would be introduced until the committee had submitted its report, but last week the Minister of Local Government and Public Health introduced a Bill which touches on several important matters concerning health. Its main provisions are two: (1) The abolition of rural district councils and the transference of their functions to the county councils; (2) the appointment for each county of a whole-time medical officer of health. These changes will be very beneficial, if they come into effect, from the point of view of health. The rural district is too small to form a convenient administrative area, and the members of its council were often too susceptible to local influences to be efficient. The appointment of whole-time medical officers of health is a reform long overdue, and one which the medical profession has long been pressing.

In the present Bill the Minister has his duties as Minister of Health laid down for the first time: "It shall be the duty of the Minister in the exercise and performance of his powers and duties, to take all such steps as may be desirable to secure the preparation, effective carrying out, and coördination of measures conducive to the health of the people, including measures for (*a*) the prevention and cure of diseases, including the avoidance of fraud in connexion with alleged remedies therefor; (*b*) the treatment of physical and mental defects, including the treatment and care of the blind; (*c*) the initiation and direction of research, and the collection, preparation, publication, and dissemination of information and statistics relating thereto; (*d*) the training of persons for health services." The Minister also seeks power to establish consultative councils to give him advice and assistance in connexion with matters of health.

The Bill, in its general principles, is on sound lines and carries a step further the reforms suggested five years ago by the Irish Public Health Council. Ardent reformers will regret that the Minister has not ventured even further, but it may be that he did not wish to forestall the advice of the Committee of Inquiry. In matters of detail, no doubt, some improvements can be made. The conditions under which pensions can be obtained in compensation for loss of office are not as clear as they might be. It appears as if the grant of a pension were still to be an act of grace rather than a right. Again, a *consultative* council is just as much or as little use as the permanent officials wish; on the other hand, an *advisory* council, with power to initiate advice, can make its influence felt more effectively, and in a way more helpful to the Minister.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Ætiology of Death at Different Age-Periods.

IN a very interesting lecture on the principal causes of death at various age-periods Prof. Pirquet showed that in the life-cycle of humanity there are several well-marked periods in which certain conditions are liable to cause trouble. Thus, in earliest childhood disturbances of nutrition, infectious diseases, and neglect of general care are responsible for the majority of deaths. Whilst in China and India about 50 per cent. of all babies die in their first year, in the European northern countries the figure is brought down to less than 10 per cent. Of the infections tuberculosis is the chief source of danger to life. In the second year of life the organism is much more resistant. But here the acute infectious diseases—scarlet fever, measles, whooping cough, and diphtheria—are the worst "scavengers." At the time of puberty the organism changes its reaction towards this disease: the lung is most apt to harbour and respond to Koch's bacilli; girls in particular are prone to these attacks, and in them the so-called "galloping phthisis" has its maximum incidence between 15 and 20 years of age. The age-incidence in youths is between 18 and 24. The same age-period shows also a maximum of deaths due to a group of constitutional diseases, which have not yet been fully investigated—namely, articular acute rheumatism, chorea, and endocarditis. Appendicitis also has its "optimum" (*sic*) at the period of puberty. In places where sanitary conditions are at a low level the worst enemy of middle age is abdominal typhus; the best prophylaxis is an abundant supply of healthy water. In Vienna, for instance, the new water-supply opened in 1871 has caused the disappearance of typhus, formerly a most common disease here. The mortality due to the dangers of pregnancy and delivery and the puerperium is highest at 30 years. The age-period of 30–60, besides chronic tuberculosis, shows already the influence of the degenerative diseases. Diabetes and Graves's disease appear as ætiological factors, and organisms weakened by syphilitic infection succumb at this period to its effects. General paralysis of the insane is most frequent at the age of 40–45, aneurysm kills its victims between 50 and 55 years, tabes at about 55–60 years. The deadly action of alcohol and lues upon the liver is most marked at about 45–55. All these conditions attack chiefly the males, as also does pneumonia, which the senescent heart can no more overcome. The females, however, are less prone to this disease, for only half as many women as men die from it at that age (55–60); on the other hand, the female organism of that age begins to feel the effects of cancer of the sexual organs (maximum incidence between 50 and 55), and the venous circulatory system of females is more enfeebled, whilst in the males it is the arterial system that suffers first. After the sixtieth year, cancer of the mouth, the intestinal canal, the other abdominal organs, and the skin appear in the ætiology of death; males are liable to arteriosclerosis, emphysema, and angina pectoris: females to chronic rheumatism, embolism, and thrombosis. At the age of 80 the brain starts to "strike," a hæmorrhage may suffice; or the kidneys, the prostate, the lungs stop their service—a slight digestive trouble or bronchitis brings the end.

Serum Dosage.

In a symposium arranged by the "College of Doctors" of Vienna, Prof. Kraus, formerly of Buenos Aires, delivered a lecture on the technique and dosage of certain therapeutic agents, which were frequently the source of uncertainty to the practitioner. The following rule, worked out by Schick and Kassowitz, Prof. Kraus said, holds good: In mild cases of diphtheria, 100 units of antitoxin; in severe cases, 500 units per kilo body-weight. Subcutaneous injection for mild, intramuscular for severe or older cases is best. The intravenous route is only used in hypertoxic cases, and is fraught with danger. The concentrated sera are better than the others, as much less frequently do they give rise to after-troubles. Even ordinary horse serum may cause albuminuria, œdema, or exanthema. Antitetanic serum is to be used in the same way as antidiphtheritic serum; it is tested nowadays by the indirect method, and its dosage is on the same lines as above. It has been found that the mortality from tetanus can be kept low by the serum, but the effect is not so brilliant as in diphtheria. Its prophylactic value is beyond question, however. Behring advised the use of 20 to 200 units, and cases with a long incubation period show the best results. Every case where tetanus infection is suspected should be treated at once prophylactically. The value of polyvalent serum against dysentery, so often recommended, has no experimental foundation. Prof. Kraus urged the prophylactic use of diphtheria serum, a method not much in favour in Vienna. A serum prepared from cattle, not from horses, is used for this purpose, and its effects are very good for producing passive immunisation; it has hardly any undesirable after-effects, not even after re-injection. As regards anaphylaxis and "serum disease," the two conditions are not identical, but conditions similar to the first-named are caused by intravenous injections of serum. Altogether, the methods are so much used and known all over the world that one should never hesitate to utilise them in prophylactic work.

Death of Prof. R. Paltauf.

Dr. Richard Paltauf, professor of pathological anatomy of the Vienna University, recently passed away at the age of 67, after a long illness. He was a pioneer of serology and micro-biology, and was an ardent adherent of Koch's methods. At an early stage of his career he made his name known by his researches on the diseases of rag-collectors, which he recognised as anthrax; on diphtheria, rhinoscleroma, and on pellagra. The pathological institute of the second largest Vienna hospital, which was put under his charge as chief when he was quite a young man, soon became the Mecca of all students of pathology. The Pasteur treatment of rabies attracted him greatly and he studied this subject in Paris, and on his return he decided to organise a similar institute in Vienna. His efforts resulted in the founding of the Austrian Institute for Prophylactic Vaccinations, which became a model for all other European centres of like nature. The production of antidiphtheritic serum in Vienna was organised by him on a large scale, when its effectivity was proved, and from this institute there emanated a long series of important papers dealing with the advances made by such researchers as Chvostek, Pirquet, Schick, Lipschütz, and Pribram. In a few years a huge serotherapeutic institute was erected, which again was the centre of attraction for all students. Important researches on the endocrine glands were made there by Biedl and Joannovics; and a number of other most important investigations pertaining to public health problems are all in a wide measure due to the zeal of this unique man. In 1903 he was appointed professor of general and experimental pathology, and published a series of papers on lympho-granulomatosis, on the liver in various conditions, and on leukæmia. His chief merit was the teaching of a staff of excellent research workers; he has actually founded a "school" of pathology. He was also an eminently patriotic man, whose soul was much depressed by the turn the political affairs took in our country; and the downfall of the empire, which he long ago predicted, left him utterly broken-hearted. His death leaves a serious gap in the phalanx of the teachers who coöperated in forming a Vienna School of medical knowledge.

CONGLETON WAR MEMORIAL HOSPITAL. — On May 22nd the Duke of York declared open the war memorial hospital built at Congleton at a cost of £13,000. It is opened free of debt and is constructed for 12 beds and four private wards.

WASTING DISEASES OF CHILDHOOD.

To the Editor of THE LANCET.

SIR,—I have read with considerable interest Dr. W. Cramer's letter in THE LANCET of May 17th, in which he suggests that in my second Goulstonian Lecture I have under-estimated the incidence of xerophthalmia in Great Britain, and over-estimated its incidence in Denmark, and that my observations "may give a wrong impression of the actual incidence of the disease and of the significance of this incidence."

My information on the incidence of xerophthalmia in Denmark was derived from the writings of Prof. C. E. Bloch of Copenhagen. In his last paper on this subject Prof. Bloch says: "Before and especially during the war, there were many cases of xerophthalmia. In a recent investigation undertaken for the Danish Ophthalmological Society by Olaf Blegvad, from 600 to 700 cases of xerophthalmia were found to have occurred between 1909 and 1920 among children, in a population of less than 3,000,000, and there were probably others."[1] The figures concerning the incidence of xerophthalmia in the Birmingham area were supplied to me by Mr. Beatson Hird, surgeon to the Birmingham and Midland Eye Hospital. The area from which the hospital draws its patients has a population of more than one half the population of Denmark, yet during the same years the number of cases seen averaged only one per year, whilst no cases were observed at the Children's Hospital.

At the time my lecture was given, Dr. Cramer's interesting address, in which he gives Dr. Marshall Findlay's experience of the occurrence of xerophthalmia (keratomalacia) in an industrial school, and its cure by giving cod-liver oil and swede juice, had not been published. Although all the cases observed in Birmingham during the period I have named were mild ones, I feel quite sure that Dr. Cramer is right when he states that mild forms of the disease may not always be recognised. His remarks on the significance of the occurrence of even a few cases of xerophthalmia are of great importance and I entirely agree with them; indeed, I hoped that I had made clear in my lectures the important part which vitamin-A deficiency may play in the wasting diseases of infancy.

I am, Sir, yours faithfully,
LEONARD G. PARSONS.

Birmingham, May 26th, 1924.

TOXIC EFFECTS OF LOCAL ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—Among the recommendations of a committee of the American Medical Association (see THE LANCET, May 17th, p. 1013) is the injunction "that cocaine paste should never be used," presumably because of its toxic effects. I do not know what exactly the committee means by "cocaine paste," but if it is the mixture that goes by that name in London, then I, for one, am at a loss to understand the downright condemnation. The paste, as we use it, consists of pure cocaine hydrochloride powder mixed with solution of adrenalin (1–1000) to the consistence of a mud or paste, and I have been employing it regularly five or six times a week for the last ten years as my mainstay in anæsthetising the nose, during the whole of which period I have not had one single case of cocaine poisoning, not even of the milder variety. This claim may seem surprising, and the surprise will not be lessened when I say that in the septum resection operation I habitually use as much as from 4 to 6 gr. of cocaine for each case. Not only so, but, when a general anæsthetic is being used for that operation, I apply the paste to the septum as a preliminary, and my anæsthetist friends can testify that that step is followed by no evils.

---

[1] Amer. Jour. Dis. Children, 1924, xxvii., 139.

The secret of safety seems to lie in the judicious use of adrenalin. In making his application let the surgeon paint the mucosa first of all with pure adrenalin solution alone and undiluted, in order to induce the local anæmia that minimises absorption, and, at the same time, denudes and exposes the sensory nerve-endings. Then the cocaine-adrenalin paste may be safely applied. It may, I think, be laid down as a rule that cocaine, whether in powder or in solution, should never be employed without adrenalin. The paste is, we must remember, not suitable for all purposes. I have never ventured to use it in the pharynx for example.

I am, Sir, yours faithfully,
DAN MCKENZIE.

Wimpole-street, W., May 22nd, 1924.

THE LATE MR. WALTER THOMPSON.

To the Editor of THE LANCET.

SIR,—May I be allowed to write a few words in memory of the late Mr. Walter Thompson, whose death was noticed briefly in your columns last week? I was his house surgeon, and later as resident surgical officer came much into contact with his cases. His work at the General Infirmary at Leeds was an example for all, the quiet methodical way in which he carried on his duties resulting in a maximum of efficiency. His keen, kindly interest in his old in-patients—whose personal history he would often know—was the admiration of those with whom he came into contact. I remember an occasion when he undertook the removal of a gangrenous appendix in a boy who had scarlet fever, and could not be moved to a nursing home owing to his infectivity. Unfortunately, in addition, a nurse was not available at the time. The operation was performed in the bedroom of a lonely farmhouse, the patient's doctor assisted, whilst I administered the anæsthetic. Notwithstanding the difficulties the operation was conducted with a perfect technique and the case did well. It was allowed by all that he was a surgeon in the broad sense; besides being an efficient operator, he knew how to decide under what conditions to operate and when not to do so, with proper adjustment of his operating measures to the condition of his patient; to this may be attributed the fact that his mortality rate was minimal. His practical knowledge of anæsthetics was of considerable value. By his death I, like many of his house surgeons, have lost a friend.

I am, Sir, yours faithfully,
A. P. BERTWISTLE.

Appleby, Westmorland, May 23rd, 1924.

PYORRHŒA ALVEOLARIS.

To the Editor of THE LANCET.

SIR,—Your review [1] of the present position of dental and alveolar sepsis in regard to general disease prompts me to make a brief comment from the pathologist's point of view.

1. The reason why there is confusion on the question as to whether dental sepsis is a cause or effect of systemic infection is, I believe, because histological examination of the blood is so frequently omitted. In this respect, I am not using the term as synonymous with the mechanical count of the corpuscles. The histology of the blood cells is often a reliable guide in the determination of the degree of systemic septic infection and is of marked assistance in the treatment of the patient.

2. As regards vaccine-therapy, I do not believe that vaccines should be expected to have any marked effect by themselves on the condition of the mouth. In my experience, however, I am not infrequently called upon to prepare a vaccine for this sole purpose. I invariably decline.

3. Given oral sepsis and histological signs of systemic infection in the blood, if one prepares an autogenous vaccine—I do not use the stock variety—from the buccal or dental lesion only it is seldom of marked benefit in systemic infection. Formerly I used to adopt this course, but after considerable experience found the results often disappointing. For some three years I have investigated the stools also, and I have found that vaccines prepared from intestinal streptococci are of much greater benefit. In other words, though I would not for a moment under-rate the necessity for turning off the oral tap by dental surgery, it appears that the streptococci from that source exert their systemic effects when they grow, as they almost invariably do, in the intestine.

I have not found the cultural characteristics, including the tests for hæmolysis, of much value as a guide to pathogenicity. A far more useful procedure is to incubate the isolated organisms with successive dilutions of normal human serum and then plant out each dilution on plates of appropriate media. Generally speaking, the strains that resist human serum in high concentration are pathogenic and vice versa. Certainly vaccines from the serum-resisting strains are of much greater clinical value.

I am, Sir, yours faithfully,
A. KNYVETT GORDON, M.B., B.C., B.A. Camb.

Bedford-square, W.C., May 24th, 1924.

TARTAR EMETIC IN BILHARZIASIS.

To the Editor of THE LANCET.

SIR,—May I draw your attention to the inaccuracy of the footnote on p. 1071? I was the first to use tartar emetic in bilharziasis, and mention is made thereof in "The Biology and Treatment of Venereal Diseases," published in 1915. Furthermore, you were good enough to draw attention to this in your columns when Dr. Christopherson published his original papers on the subject.—I am, Sir, yours faithfully,

J. E. R. MCDONAGH.

Wimpole-street, W., May 23rd, 1924.

HERPES AND VARICELLA: THEIR ÆTIOLOGICAL RELATIONSHIP.

To the Editor of THE LANCET.

SIR,—The relationship of herpes zoster to varicella is a much debated question, but in the outbreak of the latter disease to be described there seemed to be no other source of infection than contact with a case of herpes zoster. The eight children attacked had all been in a diphtheria ward of the South-Western Hospital for periods varying from 21 to 74 days. With the possible exception of the last case, who had only been in hospital 21 days, they can therefore hardly have contracted the disease before admission. A case of varicella had occurred in the ward concerned on Feb. 14th. It was promptly removed, and no further cases resulted from it, and as none of the children attacked later were in the ward at the time, they cannot have been infected by it. Other wards, under a different medical officer, in which varicella had occurred were taken out of quarantine on Feb. 24th, and there was no recognised case of varicella in the hospital after that date until May 2nd, when the outbreak about to be described occurred.

On April 17th, F. R., admitted to the ward in question on March 26th, developed typical herpes zoster, partly on the back and partly on the chest. He had a history of having had varicella some time before, and showed several good scars in confirmation. He had not been out of bed owing to his diphtheria, but was not isolated.

On May 2nd, E. C., who was admitted on March 25th from Queen Mary's Hospital, Carshalton, where he had been under treatment for tuberculous hip, and who was discharged back there on April 25th from the ward concerned, developed chicken-pox at Carshalton.

On May 3rd, H. G., admitted on March 29th to the same ward at the South-Western Hospital, and B. H., admitted on March 2nd, developed mild varicella. The latter is said to have had it before but no scars were detected. On May 4th two fresh cases occurred, one on the 5th, and two more on the 7th. Of the seven other children in the ward, five were said to have had chicken-pox, three of them showing excellent scars. The cases which make up the outbreak were all mild except two, which were moderately severe.

---

[1] THE LANCET, May 24th, p. 1063.

If the first case, E. C., contracted the disease before admission to the South-Western Hospital, it must have had an incubation period of 38 days; if he contracted it after leaving the hospital, the incubation could not have been more than seven days, both unlikely periods. On the other hand, he developed it 15 days after contact with a case of herpes zoster. Of the two children who developed varicella at the South-Western Hospital on May 3rd, one had been in the ward 35 days, the other 62 days; the next two had been in 43 and 34 days respectively; the next one 54 days; while the two who developed it on May 7th had been in 74 and 21 days respectively. This last is the only one who could possibly have contracted it outside, and there is no history of exposure. The fact that all these children had been completely isolated in a fever hospital in which there had been no recognised case of varicella since Feb. 24th must be emphasised.

The only source of infection which suggests itself is the case of herpes zoster. It is noteworthy that this patient's previous attack of varicella did not protect him from herpes zoster, although he was only 3 years old. In the cases described by Dr. H. A. Cookson, in THE LANCET of May 3rd, the patients were all over 30. That these children could have contracted varicella before admission is impossible in view of their long residence in hospital before the disease appeared, while the fact that all the cases arose 15 to 20 days after the case of herpes zoster is most significant, since this coincides with the incubation period of varicella. In fact, everything points to the case of herpes zoster as the origin of the outbreak.

I am indebted to Dr. F. Foord Caiger for permission to publish this note.—I am, Sir, yours faithfully,

AMY M. THOMS, M.D. St.And., M.R.C.P. Lond.,
Assistant Medical Officer, South-Western
May 23rd, 1924. Hospital, Stockwell, S.W.

MEDICAL DEFENCE AND PROTECTION.

To the Editor of THE LANCET.

SIR,—The recent case of Harnett *v.* Bond and Adam has excited a considerable amount of interest in the minds of the general public, and has focused the attention of the members of the medical profession on some of the many problems that may arise in the course of their daily work, and more especially on the litigation in which any member of the profession may be involved as a result of the performance of his duties to his patients and to the community at large. It has also exposed to the lay mind a possibility of securing large damages for some alleged infraction of professional treatment or procedure. The anxieties of professional life are sufficient in themselves without the addition of those inseparable from litigious proceedings.

Dr. Adam was a member of the London and Counties Medical Protection Society, and thus the responsibility of defending him was undertaken by the Society after careful investigation of the case by the Council of the Society, and he was thus relieved of the pecuniary incubus. In view of the risks run by medical practitioners in their endeavour to discharge their duties as such, it is very remarkable that all members of the medical profession do not avail themselves of the services of one or other of the two societies that are responsible for the defence and protection of their interests. It is probable that less than one-half of the medical practitioners in the United Kingdom are included in the membership of the two Societies at the present time, and it would seem to us that it is highly desirable that all practitioners should without delay join one or other of the two Societies.

We are, Sir, yours faithfully,

JOHN ROSE BRADFORD,
C. M. FEGEN.
Victory House, Leicester-sq., W.C. 2, May 27th, 1924.

THE PSYCHOLOGY OF SEA-SICKNESS.

To the Editor of THE LANCET.

SIR,—I am much interested in the remarkable explanation given by Dr. W. H. B. Stoddart (THE LANCET, May 24th, p. 1081) of the psychological origin of sea-sickness. I wonder if he could tell me whether artificial feeding interferes with the "unconscious" and renders one immune. I am a remarkably good sailor and never feel the slightest qualm, nor does my small son. We were both brought up artificially. Or is there any other explanation of the fact that some people, like Captain Corcoran, are "never, never sick at sea"? I mean an explanation from the point of view of the psycho-analyst. Is it always the psyche that is the cause of the sicky feeling?

I enclose my card, and am, yours faithfully,

May 26th, 1924. F.R.C.S.

ROYAL MEDICAL BENEVOLENT FUND.

AT a meeting of the Case Committee held recently 54 cases were considered and £614 voted to 43 applicants. The following is a summary of the new cases relieved:—

Daughter, aged 55, of M.R.C.P. Irel., L.F.P.S. Glasg. who practised in Ireland and died in 1895. She is a nurse by profession, but her health broke down five years ago. The Nation's Fund for Nurses helped her for two years but cannot continue. This case was brought to the notice of the Fund by "The Gentlefolk's Help." Voted £5.

Daughter, aged 47, of M.B. who practised in London and died in 1879. Through illness unable to help her mother, who has a boarding house and who is placed in a position of great difficulty by unavoidable debt and expense of applicant's illness. The debts are due to unsuccessful summer season. Applicant's only income last year was £17 from miniature painting and £10 from Royal Academy Fund. Voted £15.

F.R.C.P. Edin., aged 72. Medical officer until March this year, when his health completely failed. Money received up to March £246, but this has now ceased. As the applicant is not allowed to deal with correspondence or business, his wife has placed this application in the hope that the Fund will be able to give some assistance. Voted £26 in 12 instalments.

Daughter, aged 48, of M.R.C.S. Eng. who practised in Somerset and died in 1904. She had to give up her post as governess to return home to help her mother. An invalid sister who lived in Russia is now only able to earn a little by her needle. The mother is in receipt of a Fund Annuity of £20, and a paying guest, who is leaving, pays £50 for partial board. The total income this year for four people will be £80, and rent and rates amount to £42. Voted £15 in two instalments.

Daughter, aged 31, of M.R.C.S. Eng. who practised in Wales and died in 1904. She is the eldest of four children; they were brought up by their mother, whose means were very slender. When applicant left school she obtained a post as secretary. In 1915 she obtained a clerkship in a bank, but contracted tuberculosis in 1920 and was in a sanatorium for six months. Influenza this year aggravated the old trouble, and she is now confined to her bed and entirely dependent upon her mother, whose only income is £50 per annum apart from the money received from letting, which just covers rent and rates. A sister lives at home to help with the house and a brother has only had work for three months and is thinking of joining the ranks as he is unable to find employment. Voted £10.

M.R.C.S., aged 59, married, one son aged 6. Practised in Durham. Entirely incapacitated by heart failure, and is being maintained and nursed by his wife, who is using her capital to pay all expenses and school fees. The wife has placed this application as her capital is reduced to about £25, and it is a great anxiety to her and her husband. Voted £26 in two instalments.

Daughter, aged 50, of M.R.C.S. Eng. who practised in London and died in 1911. Since 1903 applicant has had to make her own way and also look after a younger brother and sister. She has supported herself by secretarial work, which is now hard to get, and she has sold her piano and all things of any value to maintain herself. She is now trying to make a fresh start, and a friend has paid a deposit on a small bungalow, taking out a mortgage in the applicant's name. She hopes the Fund will be able to give her some help, as she only received £25 from secretarial work the last 12 months, supplemented by needlework and upholstery. Voted £10.

M.R.C.S., aged 69, married. Through ill-health caused by malaria and partial loss of memory he requires attendance and constant attention. His wife was in a mental home, but has been removed to the infirmary, and is now unable to provide the 30*s.* required for her husband's maintenance. The Fund is asked to make some grant towards his expenses. Voted £26 in 12 instalments.

Daughter, aged 51, of M.D. who practised in India. Her only income is from an Indian source (£40), and she supplements this by secretarial work, which last year amounted to only £39. Her rent is 16*s.* 6*d.* per week. Applicant has a chance of work but has not a typewriter, and she asks the Fund for a grant towards a machine. The Guild joined the Fund and a grant was made of £15.

Subscriptions may be sent to the hon. treasurer, Sir Charters Symonds, K.B.E., C.B., M.S., at 11, Chandos-street, Cavendish-square, London, W. 1.

THE GENERAL MEDICAL COUNCIL:

PRESIDENT'S ADDRESS.

THE summer session of the General Medical Council was opened on May 27th, when Sir DONALD MACALISTER, the President, began by calling attention to the pleasant fact that the membership of the Council had remained unbroken since the last May session. Three former members of the Council had, however, passed away during the recess: Sir Lambert Ormsby, the eminent Dublin surgeon, who retired after a year of office in 1915; Dr. Johnson Symington, one of our great anatomists, who represented the Queen's University of Belfast from 1916 to 1919; and Dr. Henry Arthur Latimer, a Direct Representative of the practitioners of England and Wales for 13 years (1907 to 1919), who was highly esteemed both in civic and in professional life.

The Position of the Irish Free State.

The President reminded the Council of the important effects upon its membership and responsibilities exerted by recent legislation following on the establishment of the Irish Free State. "These effects," he said, "have not always been clearly foreseen by the authorities concerned, and the precise bearing of the new enactments on the provisions of the Medical and Dentists Acts is even now not easily ascertainable. We are endeavouring to obtain authoritative legal advice on the subject, and this advice I propose, with the approval of the Executive Committee, to lay before the Council in camera for its careful consideration. Meanwhile it may suffice to say that, 'unless the Government of the Irish Free State should formally communicate to His Majesty's Government their desire for the continuance' of the existing system, references direct or indirect to 'Ireland' in the Medical and Dentists Acts must henceforth be read as references to 'Northern Ireland' only. In other words, the direct relations and responsibilities of 'the General Council of Medical Education and Registration of the United Kingdom' will in future be restricted to Great Britain and Northern Ireland. The universities and medical corporations and the medical practitioners of Southern Ireland will no longer be entitled to representation on the Council. The medical qualifications granted by licensing bodies in the Irish Free State will no longer entitle the holders to be registered in the British Register; and so far as I am aware no provision has been made for the establishment of an Irish Council or an Irish Register. Some of these results cannot but be disadvantageous not only to the public health, but also to medical education and to the medical profession in Southern Ireland. A temporary continuance of existing conditions, pending the enactment of local legislation, would seem to afford at least an interim solution of the difficulty, and would offer no obstacle to the introduction by the Free State Government of a permanent measure for the regulation of medicine in Southern Ireland. We are, however, advised that, whatever changes the operation of the recent enactments may bring about, we have grounds for thinking that the present members from Ireland may sit on the Council till the expiry of the terms for which they have respectively been appointed."

Overseas and Medical Reciprocity.

The President stated that the Executive Committee had procured the adhesion of six Canadian Provinces to resolutions as to registration, bringing nearer the establishment of complete reciprocity with the Dominion. From Colonel Needham, the Official Inspector of Indian Universities and Colleges of Medicine, there had also been received a series of reports on the conditions under which registrable degrees are being conferred in India. Sir Donald MacAlister expressed his hope that the good work being done by Colonel Needham would be continued. The Executive Committee, he said, had also reported that its representations made through our Ambassador at Rome, the Foreign Office, and the Privy Council, as to the effect of recent Italian legislation upon reciprocity, are likely to have a satisfactory issue.

The London School of Hygiene.

The President announced that Sir Gilbert Barling, Dr. J. C. McVail, Sir E. Coey-Bigger, Dr. W. H. L. Duckworth, Prof. J. B. Leathes, and Sir Humphry Rolleston would act temporarily as members of a Court of Governors of the London School of Hygiene, founded with the aid of trustees of the Rockefeller Foundation and of the Government. The Executive Committee of the Council, he said, had at first considered it inexpedient that the Council should appoint its own members as Governors and thus assume responsibility for the direction of a school engaged in preparing candidates for examination in public health; but the appointments had now been made on the understanding that the charter granted to the London School of Hygiene may be shortly modified.

Statistics of the Medical Profession.

The Registrar reports that the number of new practitioners registered in 1923 was the highest on record—namely, 2482—including 244 in the Colonial and Foreign Lists. In 1918 the number of students registered was 2253; in 1919 the number rose to 3420. If we assume that of the 5673 students registered in these two years—the majority being men demobilised from the forces—some 3000 have now completed their course of medical study, it would appear that about 80 per cent. have now become qualified and registered. This corresponds very closely with the forecasts, based upon previous experience, which the Council supplied to the Government departments during the war. As after 1919 the number of new students rapidly fell, it is clear that for the next few years the numbers annually added to the Register will fall in proportion, and should soon reach the figure of 1200 or so, which was the average before the war. The comparatively small number of fresh students registered in 1923—namely, 545—is no doubt attributable to the fact that, under the new regulations of the Council, the student must now *postpone* his registration until, in addition to his Examination in General Education, he has also passed a recognised examination in Elementary Chemistry and Physics. The next year's figures will, without question, be considerably higher, and will represent more truly the actual numbers who are undergoing professional instruction for medical qualifications. The period of strain on the teaching resources of the medical schools and colleges is practically at an end. In the comparative calm which now prevails, the teaching institutions will have leisure to introduce the improvements in the medical curriculum which, with their assistance, the Council has laid down as necessary or desirable at the present time.

Finance.

Sir Donald MacAlister concluded with a word on finance. "The financial position of the Council," he said, "is improved by the large increment in the fees for registration. The accounts show that the aggregate income of the General Council and Branch Councils in 1923 exceeded the aggregate expenditure by £6177. This is the largest surplus yet recorded for any one year. As I have indicated, there are much leaner years to come; but the Council has, by reason of its economies, a sufficient reserve to face these years without misgiving, and to maintain its numerous activities for the well-being of the public and the profession in full efficiency."

Course of Business.

At the conclusion of the Presidential address the Council proceeded to the consideration in camera of a communication by the President on questions relating to the Irish Free State. Fourteen penal cases await the consideration of the Council during this session, and two cases referred from the Dental Board of the United Kingdom recommending erasure from the Register.

AN ART EXHIBITION BY MEDICAL MEN.

THERE has been opened this week at the Royal Society of Medicine a small exhibition of works of art executed by medical men. There are some 230 exhibits, comprising pictures in oil and water colour—these, as might be expected, form by far the bulk of the show, etchings, mezzotints, glass-prints, photographs—some of these are very good, and a few examples of sculpture and modelling. There are no purely medical subjects, no pathological diagrams, and no story pictures illustrating either professional devotion or family tragedy. There are almost no figure subjects, apart from the few contributions in plastic designing; the bulk of the display is made up of renderings of Nature, mostly in her sunny aspect.

The following is an alphabetical list of the exhibitors:—

Dr. H. G. Adamson.

Sir Harry Baldwin, Mr. E. A. Barton, Dr. Stanley Beale, Mr. Victor Bonney, Dr. R. J. M. Buchanan.

Mr. Herbert Charles, Dr. A. S. Cobbledick, Mr. E. Treacher Collins.

Dr. W. R. Dakin, Dr. F. G. Dawtrey Drewitt.

Mr. Arthur Edmunds, Dr. H. A. Ellis.

Dr. T. R. Glynn, Sir Rickman Godlee, Mr. H. H. Greenwood, Mr. H. B. Grimsdale.

Mr. J. Hall-Edwards, Dr. John Hay, Dr. Leonard Hill, Dr. Harold Hodgson, Mr. C. Thurstan Holland, Dr. A. F. Hurst, Mr. J. Hutchinson, Dr. T. B. Hyslop.

Sir William Lister, Dr. Cuthbert Lockyer.

Dr. J. Stewart Mackintosh, Dr. P. H. Manson-Bahr, Dr. Leonard Mark, Dr. A. H. Miller, Mr. E. Miller, Mr. J. Howard Mummery.

Mr. Humphrey Neame.

Dr. J. Porter Parkinson, Mr. G. L. Parsons, Dr. S. Vere Pearson, Mr. Joseph Pollard, Dr. R. J. Probyn-Williams.

Dr. M. B. Ray, Dr. Clive Riviere, Dr. H. Leslie Roberts, Dr. H. R. Roger-Smith, Mr. W. Rushton.

Dr. H. J. Shirley, Dr. Herbert Spencer, Mr. W. T. Holmes Spicer, Sir Squire Sprigge, Dr. Louis Starr, Mr. T. G. Stevens.

Mr. Michael A. Teale, Dr. E. Sabine Tait, Sir Charles Tomes, Mr. Fred. Turnbull, Dr. H. M. Turnbull, Mr. F. A. Tyrrell.

Mr. Kenneth Walker, Dr. William Wallace, Mr. H. M. Wharry.

No attempt is here made to estimate either the particular merits of any exhibit or the particular style and efficiency of any exhibitor, but the opinion can certainly be expressed that the average of accomplishment shown is high. This, perhaps, is not surprising, as the list just given includes the names of many who are well-known exponents of their art and of several whose work has been seen in important exhibitions.

The exhibition is being held in the buildings of the Royal Society of Medicine, in the Marcus Beck Library, and is open daily from 11 until 6 to Fellows and Members of the Society and those introduced by them. The movement has been made successful by the courtesy and interest of the President of the Society, Sir William Hale-White, by the energy of the hon. secretary, Dr. Cuthbert Lockyer, and especially by the wholehearted assistance, rendered as adjudicator and supervisor of the hanging, of Mr. Sydney Kendrick. Mr. Kendrick's advice and practical help have made the exhibition a success, and the feeling of medical men who are interested in artistic production is one of real gratitude to him for his coöperation.

KENT OPHTHALMIC HOSPITAL.—The second annual conference of the Weekly Subscribers' Fund of this hospital was held at Maidstone on May 24th. Delegates attended from all over the county, representing 47,000 subscribers. The secretary's report on the progress of the Fund was most encouraging. He stated that five years ago the income was £192, whilst last year it amounted to £7926—an increase of £699 over 1922. The miners from one large colliery had joined the Fund, and there was reason to hope that other collieries would follow suit. Every police force in the county was subscribing; a large number of post office staffs had joined; and 104 stations on the Southern Railway last year contributed £1566. Last year the number of cases seen by the surgeons at the hospital was 41,000, as compared with 778 in 1901—a notable increase.

Medical News.

UNIVERSITY OF LONDON.—At a meeting of the Senate held on May 21st, Mr. H. J. Waring, the Vice-Chancellor, being in the chair, Dr. R. A. Young was appointed to represent the University at the Tenth Annual Conference of the National Association for the Prevention of Tuberculosis to be held in London in July next.—The Graham Legacy Committee reported that Mr. V. R. Khanolkar, who had been reappointed to the Graham Scholarship for a period of two years from April 1st, 1923, had resigned the scholarship on acceptance of the post of professor of pathology in the Grant Medical College, Bombay; and that, on the recommendation of the School Committee of University College Hospital Medical School, they had appointed Mr. Norman D. Ball, of the Hospital for Consumption, Brompton, to the scholarship for two years from April 29th, 1924. The value of the scholarship is in this case £300.

EPSOM COLLEGE: SPECIAL SCHOLARSHIPS.—The Council will shortly award the following special scholarships:

The Sir Walter Buchanan Entrance Scholarship.—The value is about £33 a year. The conditions fixed by the Founders of the scholarship are as follows: The Sir Walter Buchanan Scholarship is primarily intended for the sons of deceased or prematurely invalided officers of the Indian Medical Service, or, failing any such candidates, for the sons of legally qualified medical men of pure British parentage in necessitous circumstances, who have practised medicine for at least five years in India.

Leopold Salomons Entrance Scholarships.—The value of each is £50 a year, and the conditions are that candidates shall show an adequate standard of education for their age, and that their financial condition is such as to make it impossible or difficult to obtain an education at Epsom College without the help of the scholarship. Candidates must be the sons of legally qualified medical men.

St. Anne's Home Scholarship.—The value is at present £48 a year, and it will be given to a deserving and necessitous orphan daughter of a medical man who has been for not less than five years in independent practice in England or Wales.

Forms of application for any of these scholarships can be obtained from the secretary, Mr. J. Bernard Lamb, 49, Bedford-square, W.C. 1.

PROPOSED MEMORIAL TO THE LATE SIR WILLIAM MACEWEN.—A largely attended and representative meeting was held on Thursday, May 22nd, in the Hall of the Royal Faculty of Physicians and Surgeons, Glasgow, at which it was resolved to take steps to provide a suitable memorial to the life and work of the late Sir William Macewen. Dr. A. Freeland Fergus made a preliminary statement, referring to the movement, initiated shortly before his death, to obtain a portrait of the great surgeon. It was formally resolved thereafter to promote the collection of a fund to perpetuate his memory in a fitting manner, and a number of proposals were discussed, including the following: the obtaining of a bust, relief, mural medallion, &c.; the publication of a memorial volume, including particularly Sir William Macewen's earlier scientific papers; the establishment of a Macewen Lectureship or Oration. Eventually it was remitted to an executive committee to consider these and other proposals, with a view to bringing forward to a later meeting a completed scheme. The following were elected members of this executive committee: Dr. Freeland Fergus (chairman); Prof. T. K. Monro, Sir Hector C. Cameron, Sir John Reid, Mr. J. H. Pringle (vice-chairmen); Colonel J. A. Roxburgh, Dr. George A. Allan, Sir Archibald Craig, Prof. Graham Kerr, Prof. W. K. Hunter, Dr. J. N. Marshall, Mr. William Gray, Dr. J. G. McCutcheon; and Mr. Archibald Young (hon. secretary). At the conclusion of the meeting a number of subscriptions were intimated to the treasurer, Mr. James MacFarlane, LL.D., Wesleyan-street, Glasgow, who will receive and acknowledge further contributions.

EPIDEMIC ENCEPHALITIS.—The Ministry of Health states that the total cases of encephalitis lethargica (sometimes called epidemic encephalitis or, popularly, "sleepy sickness") notified in England and Wales during the week ended May 17th has been 286, to be compared with 291 for the week ended May 10th, and 262 for that ended May 3rd. Since the beginning of the year the number of notified cases has been 2473 (as compared with an annual average of 839 in the previous four years). Out of this total, 281 have occurred in London; the chief centres affected elsewhere being Manchester, Sheffield, Birmingham, and Bristol. In general, however, the cases have been widely scattered throughout different parts of the country. It is too soon to estimate the mortality caused, but on the deaths so far reported the mortality has varied in different cities from 12 to 21 per cent. of the notified cases. The present epidemic prevalence is similar to, though more extensive than, that of the corresponding period in 1921 when a total of 1155 cases was reported. Speaking generally, there are signs of decline in the districts mainly affected, but the spread of infection to new districts results in the maintenance of the total prevalence. The existence of the disease in this country and its chief characteristics were established and described fully in reports and memoranda issued by the Local Government Board in 1918 and by the Ministry of Health in 1922. A further memorandum, about to be issued, will embody the result of the extensive inquiries now being made by the medical staff of the Ministry in different centres during the present period of prevalence. As in previous years there is little evidence that the definitely recognised cases of the disease are responsible for spreading infection, the epidemic being presumably kept up by slight and unrecognised cases or by healthy carriers of the virus of the malady. No specific measures such as vaccines are at present available either for prevention or treatment. Researches on the nature of the virus and many other problems arising in connexion with encephalitis are being actively pursued under the direction of the Medical Research Council, and in numerous laboratories at home and abroad.

IN aid of the Hertfordshire Nursing Association an Elizabethan fête will be held at Hatfield House to-day (Friday), May 30th, and Saturday, May 31st, being opened at 2 P.M. each day.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.—Further particulars of the tenth annual conference to be held in London on July 3rd and 4th (as announced in THE LANCET, March 29th, 1924, p. 678) have now been published by the Association, and may be obtained on application to the Secretary, at 20, Hanover-square, London, W. 1.

Messrs. John Bale, Sons and Danielsson, Ltd., Great Titchfield-street, W., announce for early publication the *Franco-British Medical Review*, a journal which will contain an equal number of English and French medical articles. The French articles will be translated into English, while the English articles will be translated into French, and be republished in French journals. The hope is to promote professional intercourse.

RESEARCH DEFENCE SOCIETY.—The annual general meeting of this society will be held on Friday, June 13th, at 3 P.M., 1, Wimpole-street, Cavendish-square, W., when the chair will be taken by Lord Knutsford. A satisfactory report will be submitted by the committee, and it is hoped there will be a good attendance. Dr. Andrew Balfour will demonstrate a film recently prepared by the Rockefeller Foundation, illustrating the natural history of malaria and the preventive methods against that disease. The meeting this time is being held, not at 11, Chandos-street, but at the house of the Royal Society of Medicine, where there is more room for a cinema.

PARIS: ACADEMY OF MEDICINE.—The weekly meeting on May 20th was devoted to the commemoration of the tercentenary of the birth of Thomas Sydenham. Dr. Doleris, who was in the chair, extended a cordial welcome to the three delegates from England: Dr. Sidney Phillips, treasurer of the Royal College of Physicians of London, Dr. J. A. Ryle, of the Royal Society of Medicine, and Dr. A. E. Russell, former secretary of the New Sydenham Society. Dr. Doleris emphasised the many bonds which unite medical men of England and France in common scientific interests, and spoke of the pride shared by both nations in such names as Charcot and Pasteur, Lister and Jenner. Prof. A. Chauffard, late president of the Academy of Medicine, then delivered an address on the life and work of Thomas Sydenham, an abstract of which will appear in a subsequent issue of THE LANCET.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.—Arrangements have been made for post-graduate teaching in Glasgow during the summer months—June till October. The teaching facilities are in three forms: (*a*) A general medical and surgical whole-time course, which will be conducted in a number of the general and special hospitals during the last two weeks of August and the first two weeks of September. The course is arranged to include most of the subjects of interest to the general practitioner. (*b*) Certain special clinical courses, which have been arranged in several of the hospitals to suit the requirements of general practitioners who have not very much time to devote to hospital work, (*c*) Clinical assistantships in a number of the institutions taking part in the work of the Association, which are available during the summer months as well as at other times of the year. These clinical assistantships are limited in number, and have been designed to make provision for graduates who desire opportunities for the detailed study of one or other of the "specialties." Graduates may thus become attached to wards or out-patient departments, nominally as clinical assistants. As such they will work under the direct supervision of the physician or surgeon in charge, taking advantage of the facilities for intimate study of the cases, and carrying out such detailed investigations as may be directed. These clinical assistantships provide quite exceptional opportunities for those who are able to devote the necessary time to the work, and they should appeal more especially to young graduates who contemplate practising some special subject, and to practitioners from overseas who wish to become acquainted with the methods of diagnosis and treatment employed in the various branches of medicine, surgery, and the special subjects. Copies of the syllabus, with full details of the courses, may be obtained from the Secretary, Glasgow Post-Graduate Medical Association, The University, Glasgow.

BLACKBURN INFIRMARY EXTENSION.—Blackburn's war memorial consists of an extension of the Blackburn and East Lancashire Royal Infirmary and a Garden of Remembrance. The foundation-stone of the extension was laid on May 24th by Mrs. R. A. Yerburgh. Mrs. Yerburgh and her late husband have subscribed over £31,000 to the Blackburn Royal Infirmary, which sum includes £8000 given this week. The new wing, which cost about £100,000, will have ward pavilions for 90 beds, two operating theatres, and the necessary anæsthetising, sterilising, dressing, and other rooms.

DONATIONS AND BEQUESTS.—Under the will of the late Alderman Thomas Hunter, J.P., of Leamington and Rugby, the testator left £1200 to the Hospital of St. Cross, Rugby, for a Wilfred Hunter bed in memory of his late son, and £200 to the Royal Midland Counties Home for Incurables, Leamington Spa.—The late Mr. Christian Joseph Muller, of Reigate, left by will £500 to the Royal Hospital for Incurables, Putney, and £250 to the London Hospital and the London Homœopathic Hospital.—By will the late Mrs. Ellen Cohen, of Cleveland-terrace, Hyde Park, W., left £500 to the London Ophthalmic Hospital, £500 to the Samaritan Free Hospital for Women, £500 to the Alexandra Hospital for Children with Hip Diseases, and £250 to the Surgical Aid Society.—The following bequests have been made under the will of the late Mr. Sydney Larnach, of East Grinstead: £10,000 each to the Middlesex Hospital, to St. George's Hospital, to the London Hospital, to St. Bartholomew's Hospital, to St. Thomas's Hospital, to Guy's Hospital, to the National Institution for the Blind, and to Dr. Barnardo's Homes; £5000 to Lord Mayor Treloar's Cripples Hospital and College, Alton, Hants; and £5000 to the East Grinstead Cottage Hospital.—By the will of the late Alderman Sir John Charles Bell, of Stoke Poges, the testator left £500 to the Hospital Sunday Fund, £100 each to the City of London Maternity Hospital, the Royal Surgical Aid Society, the Royal London Ophthalmic Hospital, the Royal National Orthopædic Hospital, and the Lord Mayor Treloar's Cripples Home and College. On the decease of the survivor of his wife and daughter he left £40,000 for division equally between the Infant Orphan Asylum, Wanstead; the Royal British Orphan Schools, Slough; the Orphan Working School and Alexandra Orphanage, Haverstock Hill, N.W.; the British Home and Hospital for Incurables, Streatham; the Royal Hospital and Home for Incurables, Putney; St. Bartholomew's Hospital; the London Hospital; the Hospital for Consumption and Diseases of the Chest, Fulham-road, S.W.; and the Royal Northern Hospital. The ultimate residue he left, under certain conditions, one-half as the survivor of his wife and daughter may appoint, and one-half for division between the Metropolitan Hospital Sunday Fund, the King Edward VII. Hospital Fund, the Royal Hospital and Home for Incurables, Putney, and the British Home and Hospital for Incurables, Crown-lane, Streatham.—The late Mr. Albert F. Wenger, of Newcastle-under-Lyme, left £100 to the North Staffordshire Infirmary.

THE LANCET: SUBSCRIPTION RATES.

INLAND	One Year	£2	2	0
	Six Months	1	1	0
	Three Months	0	10	6
ABROAD	One Year	2	10	0
	Six Months	1	5	0
	Three Months	0	12	6

Subscriptions not paid in advance are charged out at the published price of 1*s*. per copy, plus postage. Cheques and P.O.'s (crossed "Westminster Bank, Ltd., Covent Garden Branch") should be made payable to THE MANAGER, THE LANCET Offices, 423, Strand, London, W.C. 2.

Parliamentary Intelligence.

HOUSE OF LORDS.

THURSDAY, MAY 22ND.

Therapeutic Substances Bill.

THE Therapeutic Substances Bill was considered in Committee, the Earl of DONOUGHMORE, Chairman of Committees, in the chair.

Earl DE LA WARR moved in Subsection (2) of Clause 4 to leave out the word "and" after "General Medical Council" and to add the words, "and one member appointed by the Council of the Institute of Chemistry of Great Britain and Ireland." He explained that the addition of these words was necessary in consequence of the decision to include the Institute of Chemistry among the bodies represented on the Joint Committee which is to frame regulations under the Bill.

The Earl of ONSLOW asked why it had been suggested that the Institute of Chemistry should be added.

Earl DE LA WARR said that the Minister was advised that in view of the status of the Institute of Chemistry it was desirable that it should be included in the list. The Pharmaceutical Society was already included.

The amendment was agreed to.

Earl DE LA WARR moved an amendment to Clause 5 excluding from the operation of the Bill therapeutic substances intended to be used solely for veterinary purposes. This amendment, he said, had been agreed upon between the Ministers of Health and Agriculture.

The amendment was agreed to.

Earl DE LA WARR moved an amendment to Clause 5 providing that regulations made under the Bill should be laid before both Houses of Parliament as soon as may be after they were made.

The amendment was agreed to.

A further amendment was agreed to, the object of which was to place beyond doubt that it is an offence not merely to manufacture without a licence but also to manufacture elsewhere than on premises in respect of which a licence has been granted.

The Bill passed through Committee and was reported to the House.

HOUSE OF COMMONS.

WEDNESDAY, MAY 21ST.

Health Consultative Councils.

Mr. ROBERT RICHARDSON asked the Minister of Health whether the Consultative Councils, authorised by the Ministry of Health Act, to advise him upon matters relating to public health administration had ever been set up; if so, upon how many occasions had they met; and when was the last meeting.—Mr. WHEATLEY replied: The answer to the first part of the question is "Yes." Four Consultative Councils were set up for England and one for Wales, under Orders in Council made in 1919. The particulars asked for in the remainder of the question are as follows:—

Consultative Council on—	No. of meetings held.	Date of last meeting.
England:		
Medical and allied services ..	31	July 1st, 1921
National Health Insurance (Approved Societies' work) ..	34	March 14th, 1924
Local health administration ..	12	July 7th, 1921
General health questions ..	24	Dec. 7th, 1921
Wales:		
Welsh Consultative Council ..	15	March 18th, 1924

Compulsory Insurance by Motor Owners.

Mr. WALTER BAKER asked the Minister of Transport whether he was aware that in many cases the owners of motor-cars did not insure their cars nor themselves against third-party risks, with the result that, should an accident occur, the injured persons were unable to obtain compensation; and whether he would consider the desirability of insisting upon the compulsory insurance of all motor vehicles.—Mr. H. GOSLING replied: The question of compelling motorists to insure against accidents has been, and is still, under consideration. There are, however, practical and administrative difficulties in framing any satisfactory scheme. Legislation would be required before any such scheme could be put into operation.

Government's Housing Bill.

SIR KINGSLEY WOOD asked the Minister of Health whether he proposed to introduce a Housing Bill or make any statement on the Government's housing proposals before the Whitsuntide recess.—Mr. WHEATLEY replied: While giving no pledge on the matter, I may say that I hope to be able to introduce the Bill before the Whitsuntide recess.

Relief for Blind Poor.

Sir ROBERT ASKE asked the Prime Minister whether the Government had framed any scheme which would relieve the blind poor from being dependent on Poor-law relief.—Mr. WHEATLEY replied: No scheme has been formed for relieving Poor-law authorities of their obligation to provide relief for destitute blind persons as for other destitute persons, but every effort is made under the Blind Persons Act to prevent blind persons from becoming dependent on Poor-law relief.

Hospitals for Early Mental Cases.

Mr. COSTELLO asked the Minister of Health whether, in view of the fact that borough councils were at present empowered by the Public Health Act, 1875, to establish and maintain hospitals for any class of illness, he would consider the advisability of allocating to the health committees of local authorities grants sufficient for the provision, where desired, of hospitals for uncertifiable cases of nervous breakdown to promote their restoration to self-supporting life while avoiding the stigma associated with institutions under the control of the lunacy authorities.—Mr. WHEATLEY replied: The terms of reference to the Royal Commission will include the question of the best method of providing for the treatment of mental disorder in the incipient stage; and pending the recommendations of the Commission—which I hope will be appointed within the next few weeks—I am not prepared to introduce legislation on the subject.

Service Patients in Asylums.

Mr. COSTELLO asked the Minister of Health the total number of Service patients at present in asylums; what occupational interests were afforded them; whether any remuneration is given for extra work voluntarily undertaken by them; whether the Brabazon scheme was in operation in any asylum; and how many Service patients were discharged from asylums during the year 1923.—Mr. WHEATLEY replied: The total number of "Service" patients in county and borough mental hospitals in England and Wales on Jan. 1st, 1924, was 4623. Newspapers, books, games, &c., are provided for recreation and amusement, and such patients as are fit for it are given employment out-of-doors on the farm and gardens, and indoors in the wards and workshops. It is the practice in most mental hospitals to reward patients so employed. I am not aware that the Brabazon scheme is in operation in any county and borough mental hospital. The number of "Service" patients discharged from county and borough mental hospitals in England and Wales during the year 1923 was 217.

National Insurance Contributions.

Sir JOHN MARRIOTT asked the Chancellor of the Exchequer the amount contributed by the employers and workmen, respectively, to the National Health Insurance and to the Unemployment Insurance Fund for the year ending March 31st, 1924, or the latest appropriate date.—Mr. W. GRAHAM (Financial Secretary to the Treasury) replied: The estimated figures are:—National Health Insurance, year to Dec. 31st, 1923: Employers' contributions, £13,700,000; employees' contributions, £12,300,000. Unemployment Insurance, year to March 31st, 1924: Employers' contributions, £18,430,000; employees' contributions, £16,590,000.

THURSDAY, MAY 22ND.

Alleged Instructions to Medical Boards.

Lieut.-Colonel WOODWARK asked the Minister of Pensions whether instructions were, or had been, given to the medical officers of the Ministry of Pensions at hospitals or on boards to consider and, wherever possible, to lower the pensions of pensioners.—Mr. F. O. ROBERTS replied: No, Sir. No such instruction has been issued by my department. Perhaps I may be allowed to add that in more than 25 per cent. of all the cases examined during the past four months the assessment for pension purposes has actually been *increased*.

Medical Examination of Policemen.

Mr. HORE-BELISHA asked the Home Secretary whether he would institute a system whereby, after a constable had been medically examined by a medical practitioner for the purpose of deciding whether he was physically capable of discharging police duties, he should be informed in writing that if he wished to appeal on medical grounds against the decision of the medical practitioner he had the right to lodge an appeal within 14 days; whether all medical practitioners could be instructed to take the constable's service into account and the consequent natural deterioration of his physical powers in their medical findings; and whether, in all cases before a constable was dismissed upon the grounds of ill-health, the question of his dismissal could be considered in relation to his pension rights and efforts be made to give him a lighter form of employment in order that he might complete his time for pension.—Mr. Henderson replied: As regards the first part of the question, the suggested notice in each individual case would appear unnecessary if, as I presume, the police are generally aware of the existence of the appeal procedure. I will, however, take steps to make sure that this procedure has duly been brought to the notice of the members of all forces. As regards the second part, the question the medical practitioner has to consider is whether the constable is or is not incapacitated by infirmity for further police duty, and whether such incapacity is likely to be permanent; and the length of the constable's service may or may not be relevant thereto. The question raised in the third part must be left to the police authorities to decide.

Blind Persons and Health Insurance.

Sir Charles Barrie asked the Minister of Pensions if he was aware that, under the National Health Insurance Act, should a person become incapacitated, but nevertheless be able to do light work, he was unable to draw any weekly allowance on account of performing light duties, and that this had been applied to people who were incapacitated by blindness; and would he introduce legislation to remove this disability in such cases.—Mr. Greenwood (Parliamentary Secretary to the Ministry of Health) replied: An insured person who has, through blindness or any other cause, been rendered permanently incapable of following what was formerly his normal occupation is not entitled to continue to receive sickness or disablement benefit under the National Health Insurance Acts after he has become capable of following some other remunerative occupation which is reasonably open to him, either at once or as the result of a course of training. My right hon. friend does not think it desirable to introduce legislation to enable benefit to be paid to persons who are undertaking remunerative work.

Advisory Committees on War Pensions.

Mr. Ernest Brown asked the Minister of Pensions the composition of the newly proposed advisory committees on war pensions.—Mr. F. O. Roberts replied: The scheme for the constitution and procedure of the new advisory councils is at present in draft and is the subject-matter of discussion at the series of Conferences which I am holding, in certain important centres, with representatives of war pensions committees. I may say, however, that it is intended that the new councils shall include one representative appointed on the nomination of each war pensions committee in the area covered by the council, together with direct representatives of disabled ex-Service men, widows, and dependents.

Friday, May 23rd.

Welfare of Blind Persons.

Mr. T. Henderson moved the second reading of a Bill to amend the Blind Persons Act, 1920. It proposed, he said, that every blind person who had attained the age of 30 should be entitled to receive and continue to receive such pension as under the Old Age Pensions Act he would be entitled to receive if he were 70 years of age. The present pension age was 50. County councils and county borough councils were to make arrangements to the satisfaction of the Ministry of Health for promoting the welfare of blind persons ordinarily resident within their area by providing and maintaining workshops and hostels and homes for them. Those employed in the workshops were to be paid remuneration not less than the average standard rate received by unskilled labourers in the district. The number of blind persons in England and Wales from one year upwards was 36,578. Those trained and employed were 8239; those under training were only 1246; and those unemployed who were between the ages of 30 and 70 numbered 20,759.

Mr. F. Martin, the blind Liberal Member for East Aberdeen, who was received with loud cheers, seconded the motion for the second reading.

After some discussion,

Mr. A. Greenwood (Parliamentary Secretary to the Ministry of Health) said that the Government attached very considerable importance to steps for the prevention of blindness. To that question the Minister of Health was now giving his attention. He was not prepared to say that the Government would accept the details of the Bill, although they were in sympathy with its objects. The Government would give their sympathetic consideration to the future of the measure.

The Bill was read a second time without a division.

Monday, May 26th.

Financial Grants to Hospitals.

Mr. Potts asked the Chancellor of the Exchequer whether, from his Budget surplus, he could make an additional grant of £1,000,000 to the hospitals of the country, having special regard to industrial centres where hospitals were in serious financial difficulties.—Mr. W. Graham (Financial Secretary to the Treasury) replied: The demands that have already been made on my right hon. friend's Budget surplus leaves him little scope for accepting fresh liabilities of this kind.

INFECTIOUS DISEASES IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 17TH, 1924.

Notifications.—The following cases of infectious disease were notified during the week—namely, small-pox, 116; scarlet fever, 1500; diphtheria, 723; enteric fever, 95; pneumonia, 924; puerperal fever, 24; cerebro-spinal fever, 14; acute poliomyelitis, 7; acute polioencephalitis, 2; encephalitis lethargica, 286; continued fever, 2; dysentery, 4; ophthalmia neonatorum, 143. There were no cases of cholera, plague, or typhus fever notified during the week. The number of notified cases of encephalitis lethargica is practically the same as last week, the largest number of notifications coming from the counties of London, Durham, Gloucester, Lancaster, Middlesex, Northumberland, Stafford, Warwick, Yorkshire (West Riding), and others in smaller number. Of the cases of small-pox 63 were notified from the county of Derby (46 of these from Chesterfield), 13 from Northumberland (11 from Ashington), 12 from Nottingham (Hucknall and Basford each 5), Yorks, North Riding 13 (all from Middlesbrough).

Deaths.—In the aggregate of great towns the deaths from influenza fell further from 95 to 73. There were only 6 deaths in London from diphtheria, 23 from measles, and 5 from influenza.

The Services.

ROYAL ARMY MEDICAL CORPS.

OFFER OF COMMISSIONS.

Twenty or more Commissions in the Royal Army Medical Corps will be open for competition by examination on July 30th next. Applications for admission to the examination must be made to the Under Secretary of State, the War Office, Whitehall, London, S.W. 1, not later than July 20th, and the presence of candidates will be required in London from July 28th. Students who have entered for their final professional examinations in July may submit applications, which will be accepted subject to candidates qualifying and being registered before July 30th.

TERRITORIAL ARMY.

Capt. R. B. Smith resigns his commn. and retains the rank of Capt.

Supernumerary for Service with O.T.C.—Capt. (Local Maj.) C. H. Budd to be Maj.

ROYAL AIR FORCE.

Flight Lt. T. J. D. Atteridge is granted a permanent commission.

INDIAN MEDICAL SERVICE.

The King has approved the retirement of Lt.-Col. V. E. H. Lindesay.

Medical Diary.

Information to be included in this column should reach u in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Thursday, June 5th.

OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.

Specimens:

Dr. H. Russell Andrews: Lipoma Ulcerating through the Vagina and Causing Severe Hæmorrhage in a Girl of 19.

Dr. J. S. Fairbairn }
Dr. J. Taylor } Simple Ovarian Embryoma with Spread into Contiguous Structures.

Paper:

Professor J. Munro Kerr
Dr. McIntyre
Dr. James Hendry
} Wounds of the Gravid and Non-Gravid Uterus—a Study of Uterine Scars.

(1) Professor Munro Kerr will discuss the subject from the clinical standpoint.

(2) Dr. McIntyre: Histological Studies of Various Uterine Scars.

(3) Dr. Hendry: Observations on the Uterine Scar after Conservative Cæsarean Section:—(*a*) When the Incision was made in the Active Contractile Portion of the Uterus. (*b*) When the Incision was made in the Lower Uterine Segment.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, June 2nd, to SATURDAY, June 7th.—CHELSEA HOSPITAL FOR WOMEN. Daily Operations, &c. Wed., 4 P.M., Mr. John Ellison: Minor Displacements. Fri., 2 P.M., Mr. J. B. Banister: Cervical Polyps.—LONDON SCHOOL OF TROPICAL MEDICINE. Tuesdays and Thursdays, 2 P.M., Demonstrations on Diseases of Tropical Countries.—MAUDSLEY HOSPITAL. Wed., 2.30 P.M., Dr. Mapother: Delusional States.—ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN. Clinical Demonstrations Daily (except Sats.) at 2 and 6 P.M.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, W. 1.

FRIDAY, June 6th.—9 P.M., Lord Rayleigh: The Glow of Phosphorus.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE.

MONDAY, June 2nd.—12 noon, Dr. Greenfield: Lecture, Cellular Reaction in Nervous System. 2 P.M., Dr. Hinds Howell: Out-patient Clinic. 3.30 P.M., Dr. Aldren Turner: Clinical Lecture.

TUESDAY, June 3rd.—12 noon, Dr. Walshe: Lecture, Anatomy and Physiology of Nervous System. 2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Mr. Armour: Compression Paraplegia.

THURSDAY, June 5th.—12 noon, Dr. Riddoch: Lecture, Anatomy and Physiology of the Nervous System. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Hinds Howell: Lecture, Subjective Disorders of Sensibility.

FRIDAY, June 6th.—2 P.M., Dr. Gordon Holmes: Out-patient Clinic. 3.30 P.M., Mr. Sydney Scott: Lecture, Recent Studies on the Vestibular Nerve.

Applications should be addressed to the Secretary, Medical School, National Hospital for the Paralysed and Epileptic, Queen-square, London, W.C. 1.

J. G. GREENFIELD, Dean.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, June 2nd.—12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Addison: Surgical Wards. 2 P.M., Mr. Bishop Harman: Eye Dept.

TUESDAY.—11 A.M., Dr. McDougal: Electrical Dept. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY.—12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Owen: Medical Out-patients. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 12 noon, Dr. Scott Pinchin: Diseases of the Heart. 2 P.M., Mr. Simmonds: Surgical Out-patients.

FRIDAY.—12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Dr. Burrell: Medical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose, and Ear Dept.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M. In-patients, Out-patients, Operations, Special Departments.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, June 5th.—4 P.M., Dr. Paterson: Vomiting.

ST. JOHN'S HOSPITAL, Leicester-square, W.C.

TUESDAY, June 3rd.—5 P.M., Dr. Bunch: Lupus.
THURSDAY.—5 P.M., Dr. M. G. Hannay: Lichen Planus.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.

THURSDAY, June 5th.—5 P.M., Mr. Richard Lake: Middle-Ear Disease. (Geoffrey E. Duveen Lectures in Otology.)

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)

MONDAY, June 2nd.—(At the Children's Hospital.) Mr. McMurray: Tubercular Arthritis.

TUESDAY.—(At the Southern Hospital.) Mr. O. H. Williams: Carcinoma of the Colon.

WEDNESDAY.—(At the Northern Hospital.) Dr. A. A. Gemmell: Ectopic Gestation.

THURSDAY.—(At the Stanley Hospital.) Mr. Courtenay Yorke: Ear, Nose, and Throat Cases.

FRIDAY.—(At the Royal Infirmary.) Mr. Thelwall Thomas: Treatment of Enlarged Prostate.

BRISTOL UNIVERSITY POST-GRADUATE DEMONSTRATIONS.

WEDNESDAY, June 4th.—(At the Hereford General Hospital). 3.30 P.M., Dr. J. O. Symes: Mental Deficiency and Feeble-mindedness in Children.

Appointments.

BUIST, J. J., M.B. Lond., has been appointed Teacher of Vaccination to the Welsh National School of Medicine.

DUNN, W. J., M.B., B.Ch. Belf., Dispensary Doctor of Donamena, Co. Tyrone.

EDGE, W., M.R.C.S., L.R.C.P. Lond., Resident Medical Superintendent at the Ladywell Sanatorium, Weaste.

MCCOLGAN, F. P., F.R.C.S. Irel., Medical Officer for the Laghey Dispensary District, Donegal.

MACDONALD, R., M.D. Edin., Medical Superintendent of the Coton Hill Mental Hospital, Stafford.

WHEELER, D. R., M.B., F.R.C.S. Eng. & Irel., Throat Surgeon, North Middlesex Hospital.

St. Thomas's Hospital: FISHER, J. H., M.B., B.S. Lond., F.R.C.S. Eng., Consulting Ophthalmic Surgeon; HUDSON, A. C., M.D., B.Ch., F.R.C.S. Eng., Ophthalmic Surgeon; DOYNE, P. G., M.B., B.Ch. Oxf., F.R.C.S. Eng., Ophthalmic Surgeon in Charge of Out-patients; DE WESSELOW, O. L. V. S., M.B., B.Ch. Oxf., F.R.C.P. Lond., Physician in Charge of Out-patients; LEYS, D. C., M.B. Oxf., M.R.C.P. Lond., Resident Assistant Physician; ROSS, D., M.B., B.Ch. Camb., Officer in Charge of Psycho-Therapeutic Dept.; FILDES, G., M.B., Ch.B. Manch., D.M.R. and E. Camb., Officer in Charge of X Rays Department: HOPE-SIMPSON, J. W., M.B., B.Ch. Camb., YATES, H., M.R.C.S., L.R.C.P. Lond., CREED, R. S., M.B., B.Ch. Oxf., BERRIDGE, W. C. M., M.R.C.S., L.R.C.P. Lond., JEFFERY, A. L. P., M.B., B.S. Lond., WALFORD, A. S. H., M.B., B.Ch. Camb., WEBB-PEPLOE, M. H., M.B., B.Ch. Camb,. and METCALFE, G. A., M.B., B.Ch. Camb., Casualty Officers and Anæsthetists; DYSON, A. D., M.R.C.S., L.R.C.P. Lond., MURRELL, E. B., M.R.C.S., L.R.C.P. Lond., COOPER, G. K., M.B., B.Ch. Camb., and PALMER, H. M., M.R.C.S., L.R.C.P. Lond., House Physicians; STORY, A. G., M.B., B.Ch. Camb., House Physician (for Children); LAUTRÉ, M. A., M.R.C.S., L.R.C.P. Lond., LUPTON, C. A., M.R.C.S., L.R.C.P. Lond., BRIGGS, T. F., M.R.C.S., L.R.C.P. Lond., and WILLIAMS, L. G., M.R.C.S., L.R.C.P. Lond., House Surgeons; ALLAN, F. G., M.R.C.S., L.R.C.P. Lond., Orthopædic House Surgeon; PEARCE, T. V., M.B., B.S. Lond., and JONES, B. H., M.R.C.S., L.R.C.P. Lond., House Surgeons for Throat and Ear respectively: CROCKFORD, A. L., M.B., B.Ch. Camb., Senior Obstetric House Physician; CHADWICK, S. A. R., M.R.C.S., L.R.C.P. Lond., Junior Obstetric House Physician; PENMAN, G. G., M.R.C.S., L.R.C.P. Lond., Senior Ophthalmic House Surgeon; BATTSON, A. A., M.R.C.S., L.R.C.P. Lond., Junior Obstetric House Surgeon; CAVENAGH, J. B., M.B., B.Ch. Oxf., NEILSON, D. F. A., F.R.C.S. Eng., HUDSON, M. W. P., M.R.C.S., L.R.C.P. Lond., STARKEY, R. S., M.R.C.S., L.R.C.P. Lond., BARRON, H. T., M.D. Lond., FACEY, R. V., M.B., B.Ch. Oxf., NAUDE, A. L. te W., M.R.C.S., L.R.C.P. Lond., MARRINER, H. I., F.R.C.S. Edin., REES, E. J., M.R.C.S., L.R.C.P. Lond., SIMS, T. H., M.R.C.S., L.R.C.P. Lond., ALEXANDER, R. D., M.R.C.S., L.R.C.P. Lond., DARLINGTON, A. F. D., M.R.C.S., L.R.C.P. Lond., MORRIS, E. G., M.R.C.S., L.R.C.P. Lond., WEAVER-ADAMS, E. R., M.R.C.S., L.R.C.P. Lond., HALLIWELL, C. C., M.R.C.S., L.R.C.P. Lond., COOKE, A. M., M.B., B.Ch. Oxf., LANKESTER, A. L., M.R.C.S., L.R.C.P. Lond., MCLEAN, W. W., M.R.C.S., L.R.C.P. Lond., THORP, K. W., M.R.C.S., L.R.C.P. Lond., DOGGART, J. H., M.R.C.S., L.R.C.P. Lond., DAVIES, D. V., M.R.C.S., L.R.C.P. Lond., HOCHSCHILD, G., M.R.C.S., L.R.C.P. Lond., BRITO-MUTUNAYAGAM, M. A. B., M.R.C.S., L.R.C.P. Lond., and BAUWENS, P., M.R.C.S., L.R.C.P. Lond., Clinical Assistants.

Leicester Royal Infirmary: SLIGHT, J. D., M.D. Edin., Hon. Physician; CAIRNS, M.D. Edin., Asst. Hon. Physician.

Certifying Surgeons under the Factory and Workshop Acts: SUTHERLAND, W. D., M.B., Ch.B. Glasg. (Burghead District of Moray); MALCOLM, J., M.B., C.M. Aberd. (Kemnay, Aberdeen); CLOUSTON, E. C. T., M.R.C.S., L.R.C.P. Lond. (Lavenham); and JONES, J. H. (Kidwelly).

Vacancies.

For further information refer to the advertisement columns.

Barbados General Hospital.—Res. S. £330.

Barrow-in-Furness, North Lonsdale Hospital.—H.S. £225.

Bristol Maternity Hospital, Brunswick-square.—Visiting P. and two Asst. P's.

Bristol Royal Infirmary.—Hon. P. and Hon. Asst. P.

Bristol University.—Professorship of Medicine including Directorship of Clinical Studies.

Buxton, Devonshire Hospital.—Bacteriologist. £400.

Cairo, Egyptian Government School of Medicine.—Prof. of Biology. L.E.900–1140.

Chichester, Graylingwell Mental Hospital.—Second and Third Asst. M.O.'s. £350 and £300 respectively.

Guy's Hospital, S.E.—Director of Dept. for Venereal Dis. £500.

Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—H.P., H.S., Cas. M.O., and Cas. Surg. O. Each £100.

Holland County Council, Lincolnshire.—Asst. County M.O. £600.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each £50.

Huddersfield, Storthes Hall Asylum, Kirkburton.—Asst. M.O. £400.

Lancashire County Mental Hospital, Winwick, Warrington.—Locum Tenens M.O. 8 guineas weekly.

L.C.C. Mental Hospitals.—Seventh Asst. M.O.'s. £440.

London Hospital, E.—First Asst. to each of the four Medical Firms. £400.

London Hospital Medical College.—Jun. Demonstrator of Physiology.

London Lock Hospital, 91, Dean-street, S.W.—Clin. Assts.

London Temperance Hospital, Hampstead-road, N.W.—R.M.O. £200.

Middlesex Hospital, W.—Physn. to Dept. for Dis. of Nervous System.

Newcastle-upon-Tyne, Princess Mary Maternity Hospital, Jubilee-road, City-road.—Asst. R.M.O. £40.

Nottingham General Hospital.—H.P., H.S., also H.S. for Ear, Nose, and Throat Dept. Each £150.

Oldham Royal Infirmary.—Three H.S.'s. Each £200.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Obstet. S.

Queen Mary's Hospital for the East End, Stratford, E.—Hon. Asst. P.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Dental S. £300.

Royal Army Medical Corps.—20 Commissions.

Royal Chest Hospital, City-road, E.C.—P.

Royal Northern Hospital, Holloway, N.—Anæsthetist. 10 guineas.

St. Albans, Herts Mental Hospital, Hill End.—Locum Tenens Asst. M.O. 7 guineas weekly.

St. Bartholomew's Hospital, E.C.—Radiologist.

St. Marylebone Hospital, Ladbroke-grove, W.—Third Asst. M.O. £300.

St. Pancras Hospital, King's-road, N.W.—Jun. Asst. M.O. £350.

Salford Royal Hospital.—Res. M.O. £175.

Sheffield Royal Infirmary.—Ophth. H.S., H.S., Asst. Cas. O., and H.S. to Ear, Throat, and Nose Dept. Each £60.

South London Hospital for Women, Clapham Common, S.W.—Asst. P.

Stirling District Mental Hospital, Larbert.—Third Asst. M.O. £250.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—Sen. Res. M.O. £250.

War Memorial Hospital, Enfield, Middlesex.—Hon. Radiologist.

West Bromwich and District Hospital.—Res. H.S. £220.

West London Hospital, Hammersmith-road, W.—H.P., H.S., Aural H.S., Res. Cas. O., and Med. Reg. Each £100.

Western Dispensary, 38, Rochester-row, Westminster, S.W.—Vacancy on Attending Medical Staff.

Births, Marriages, and Deaths.

BIRTHS.

CRANE.—On May 19th, at Bournemouth, the wife of Walter A. Crane, L.D.S., of a daughter.

RUSSELL.—On May 24th, at Southsea, the wife of Major G. Blakeley Russell, R.A.M.C. (retd.), Turret House, Portchester, of a daughter.

WALFORD.—On May 21st, at Wigmore-street, the wife of Dr. Alfred S. H. Walford, of a son.

WATSON.—On May 21st, at Cheltenham, the wife of Lt.-Col. C. H. Watson, D.S.O., I.M.S. (retd.), of a daughter.

MARRIAGES.

BLAKE—WRIGHT.—On May 22nd, at Christ Church, Westminster, Eliot Watson Blake, M.R.C.S., L.R.C.P., to Hilda Margery Wright, youngest daughter of the late Rev. Alban Wright, M.A., and the late Mrs. Wright, of Bedford.

LAIRD—SCOTT.—On May 20th, at St. Columba's, Pont-street, S.W., David Anderson Laird, F.R.C.S.E., of Southport, to Marion, youngest daughter of the late Rev. Adam and Mrs. Scott, of Sale and Southport.

SMART—EVANS.—On April 30th, 1924, at St. Peter's Church, Sible Hedingham, Arthur Herbert John Smart, M.B., B.Ch. Camb., to Amelia Olwen Mona Evans.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

LINKS WITH THE PAST.*

BY SIR J. KINGSTON FOWLER, K.C.V.O., C.M.G., M.D. CAMB.

[THE lecturer, after congratulating the Society on being the oldest hospital medical society in London and on having nevertheless retained the vigour of youth, discussed some of the links binding the Middlesex Hospital and King's College Hospital, referring especially to James Moncrieff Arnott and Dr. Thomas Watson.]

James Moncrieff Arnott was one of the founders of the medical school of the Middlesex Hospital and was for many years one of its surgeons. He was one of the original Fellows of the Royal College of Surgeons of England in 1843.

Sir Thomas Watson was a Tenth Wrangler and a Fellow of his College at Cambridge. He was physician to this hospital from 1827 to 1843, and in 1843 he published his "Lectures on the Principles and Practice of Physic," a book which 50 years ago was read by nearly all students.

Cardiology, Old and New.

It must have been chiefly in the wards of this hospital that Sir Thomas Watson acquired the clinical experience which enabled him to write those lectures, which were delivered partly at King's College and in part to the students of this hospital. I can claim a slender link with Sir Thomas Watson in that on Jan. 27th, 1888, I read a paper before the Clinical Society of London entitled a Case of Disease of the Aortic and Mitral Valves of 54 Years' Duration, originally under the Care of the late Sir Thomas Watson. It was that of a man aged 66, a wood turner, who in 1834, being then a boy aged 13, was admitted to this hospital with an attack of acute rheumatism, for which he remained under treatment for nine months and was readmitted with a relapse for a further period of six months. During 53 years he worked a treadle lathe as a wood turner, and had only been laid up on one occasion for a day or two with a slight cold. He had not experienced any shortness of breath on exertion. His family had not been usually long-lived or exceptionally vigorous. The physical signs indicated a moderate degree of narrowing of the aortic orifice, and that the aortic and mitral valves were incompetent. An enlarged area of præcordial dullness with well-marked systolic recession of the epigastrium and fifth and sixth interspaces suggested, but did not prove, that there were adhesions between the surfaces of the pericardium.

I stated in my paper that there could be little doubt that this was a case of valve disease of rheumatic origin, in which compensation had been established, had remained perfect for 54 years, and still showed no sign of failure. The symptoms of valvular disease depend upon failure of compensation; here there had been no failure, and consequently there had been no symptoms. The patient was admitted into the Middlesex Hospital under the care of my colleague, Dr. Sidney Coupland, on March 27th, and died on May 27th, 1888. At the autopsy the condition of the heart was shortly as follows: The surfaces of the pericardium were universally adherent. The heart weighed 20¼ oz. The left auricle and appendix were dilated, the edges of the mitral flap were much thickened; two of the chordæ contained calcareous deposits in their substance; the orifice was narrowed and the valve incompetent. The left ventricle was hypertrophied and dilated. The free margins of the aortic cusps were thickened, deformed, and contracted, so as to produce a slight narrowing of the orifice, and to permit of a moderate amount of regurgitation. There were numerous calcareous plates in the aorta. The kidneys were granular on the surface, and the cortex contained some cysts.

How faithful this patient was to the hospital. Brought to it as a boy, doubtless by his mother, he returned after the relapse, and again after an interval of 54 years of good health, and then for the last time to die within its walls. How typical of one of the most marked characteristics of the English race, an attachment to local institutions. This case has also an additional interest in that it proves, in contradiction to what we have heard somewhat often of late, that 37 years ago it was a matter of common knowledge amongst physicians that the prognosis in valvular disease of the heart did not depend upon the exact time of a murmur or upon the valve which was affected, but upon the condition of the muscular tissue of the heart, as evidenced by the capacity of the patient for physical exertion and upon the presence or absence of what is called "failure of compensation."

---

* Abstracted from an address delivered on May 22nd to the Middlesex Hospital Medical Society on the occasion of the 150th anniversary of its foundation.

Early Theories on High Blood Pressure.

It is to my mind an easy transition from Sir Thomas Watson to Dr. (afterwards Sir) George Johnson, physician to King's College Hospital, whose memory I revere as my first master in medicine. Sir George Johnson was a master in the use of the stethoscope, and from him I learned the importance of diagnosis in clinical medicine. The public are but little interested in diagnosis, but great authorities on treatment. Yet it would appear at first sight that before the treatment of a patient is considered, a knowledge of the nature of his malady is not out of order. Sir George Johnson has a special claim upon those of you who are about to enter upon the practice of the profession, as you will enjoy an advantage denied to nearly all your predecessors in that you will find that most of your patients are suffering from the same ailment. It is hardly necessary to state that this is blood pressure. This great advantage you owe to Sir George Johnson.

In the preface to his last work he states that "the discovery of the structure and function of the arterioles and of the vaso-motor nervous system has thrown an entirely new light upon pathological subjects so entirely diverse and apparently disconnected as, amongst others, (1) Raynaud's disease; (2) the immediate cause of the arrested circulation and death from apnœa, badly named asphyxia; (3) the true nature and proximate cause of the collapse stage of cholera; and (4) the cause of hypertrophy of the left ventricle of the heart, which is so frequently associated with the contracted granular kidney. The connecting link between these diverse conditions is the 'stop-cock action' of the muscular-walled arterioles, the systemic arterioles being concerned in the first and fourth of the above-mentioned pathological conditions, and the pulmonary arterioles in the second and third."

The stop-cock function of the arterioles and the resulting high blood pressure in chronic Bright's disease are explained as follows: "In my endeavour to explain the cardiac hypertrophy it occurred to me that the impediment to the systemic circulation which calls for more forcible contraction, with resulting hypertrophy of the left ventricle, might be due to a persistent general contraction of the systemic arterioles, this contraction being excited by the abnormal quality of the blood. Then it seemed reasonable to infer that the long-continued over-action of the arterioles would result in hypertrophy of their muscular walls; and, guided by this line of reasoning, I was led to the discovery that the walls of the arterioles are hypertrophied, not only in the kidneys, where I first discovered and described it 17 years before, but also in the skin, the intestines, the voluntary muscles, and the pia mater."

In opposition to the views of Dr. Johnson, Sir William Gull and Dr. Sutton regarded the changes in the arterioles as due to a hyalin-fibroid change and not to hypertrophy of the muscular walls, the result of persistent contraction. This was then and has since been spoken of as arterio-capillary fibrosis, and is the condition present in what is now termed diffuse hyperplastic sclerosis.

The present view of this question, which was the subject of prolonged controversy, is somewhat as follows: Greater importance is attached to the changes in the intima than in the media, and the primary lesion is believed to be in the intima of the smaller and smallest arteries. The hypertrophy of the middle coat, which Dr. Johnson was the first to demonstrate, is admitted, and the changes in both coats is earlier and more marked in the kidney than elsewhere. The hypertrophy of the middle coat is regarded as a physiological response to the increased blood pressure. I do not find in the most recent literature of this subject a recognition of the fact that the hypertrophy of the left ventricle may be just as marked after death, in a case of acute scarlatinal nephritis of some months duration, as it is in chronic interstitial nephritis, and this I regard as the crux of the problem, for in such case there is no doubt as to the renal nature of the primary lesion. The clinical teaching of Dr. George Johnson remains in my judgment as sound to-day as it was 50 years ago.

[The lecturer then described briefly the services to the Society and to the medical school of Andrew Clark, President at the date of the centenary celebration, Alexander Patrick Stewart, Henry Thompson, Edward Headlam Greenhow, Robert Liveing, William Cayley, John Whitaker Hulke, George Lawson, David White Finlay, Thomas Henry Kellock, Robert Henry Lucas and Edward Ashby Fardon, John James Pringle, Robert Wishart Lyell and Charles Leopold Hudson, and Alfred Pearce Gould. He discussed the advances in medicine during the last 50 years, laying special stress on the treatment of acute rheumatism, the prevention and treatment of enteric fever, and the recognition and control of myxœdema. He discussed also the diminution in the use of alcohol in disease and proceeded finally to consider medical research.]

Research.

For the last 15 years it has been my good fortune as hon. secretary, a member of the advisory board, and a trustee of the Beit Fellowship for Medical Research, to have been in close contact with some of those who have taken part in the work of research. To have had such an opportunity, and yet to have come to no conclusions as to how the results which we all desire can best be achieved, would almost be deserving of censure, and I cannot plead such an excuse. When I see on the wall of the building which stands next to that in which we are now assembled, "The Bland-Sutton Institute of Pathology," I see therein embodied all the conclusions at which I long since arrived. To bring together young men imbued with that rare spirit of research and the ability which is so necessary for its prosecution in its highest forms, under a guiding mind who will point out the lines which should be followed, and help to overcome the obstacles which will almost constantly be met with, and to give the encouragement necessary when failure seems to be inevitable—that is my conception of the right way.

In such an atmosphere the work of one man unexpectedly throws light upon that of another, although the researches upon which they are severally engaged appear to be far as the poles asunder. Therein is acquired that knowledge of laboratory technique which is an essential preliminary to success in research, whereas its absence is an almost certain prelude to disaster. It is quite true that it would be possible to tell of many whose names in science are world-wide who did not enjoy the amenities which such an institute affords. The broken-down walls of the old Ecole Normale where Pasteur worked and Lister's Ward in Glasgow Infirmary were not models for future generations to copy, but the lack of many things which they and others needed only hindered their work, it did not help it forwards. They were able by their genius to triumph over the unnecessary difficulties by which they were surrounded.

It is possible that one of those to whom I am now speaking may, when our Society celebrates the completion of 200 years of honoured life, stand in my place and recall the great deeds of science which have marked the 50 years which will then have come to an end. And I do not doubt that he will be able to point to far greater triumphs than have this evening been recalled to your minds, for we are but on the threshold of that garner of knowledge which is called medical science. But let it never be forgotten that the art and practice of medicine in every age have to deal with human nature, which changes but slowly and will never rise above the need for sympathy and kindness in times of sickness, or when about to enter the realms of the eternal silence.

UNBREAKABLE SURGICAL NEEDLES.

Mr. Hamilton Bailey, F.R.C.S., writes: In every branch of operative surgery the breaking of needles has been a source of annoyance, delay, and even danger. I have had needles so tempered that they will not break even when subjected to a much greater stress than is probable in any surgical procedure. Other advantages of these needles are: (1) Being malleable, with two pairs of watchmaker's pliers or (but not so accurately) with Spencer Wells forceps, a needle may at any moment be fashioned to such a curvature as to meet a particular situation in hand; (2) by exerting moderate lateral pressure upon the threaded "eye"—the suture may be "locked" within the needle—thus eradicating another evil—the needle becoming unthreaded. It was Mr. Thelwall Thomas, of Liverpool, who first directed my attention to the possibilities of a needle or bodkin the centre of which had been rendered malleable by being held in a flame.

Messrs. P. Spencer and Sons, surgical needle manufacturers, of Redditch, are the makers.

"THE SHOT."[1]

THE medical interest of this book is not very profound and largely turns upon the question of whether a neurotic, whose character is well indicated in a few lines, was murdered, and, if so, by whom; or whether he shot himself. The solution of the mystery, which is well sustained to the end of a cleverly told story, would not wholly satisfy forensic medicine, but it is the logical termination of some complicated events which are well thought out and arranged coherently. The author has hit upon a new and good plot and has developed it well, writing clearly and forcibly, and getting and preserving a real atmosphere, but in future efforts she might be asked to keep guard over two things. The first is the perpetual use of the historic present, which has so much point when employed occasionally and is so irritating in continuous narrative; the second is, the little trick of asking the reader questions which are generally answered in the next line. The question and answer constitute statements which might as well be made directly. The pleasure given by the good sensational novel is now widely acknowledged by the most serious folk, and we recommend "The Shot" to our readers.

HEALTH CONDITIONS IN SOMALILAND AND THE STRAITS SETTLEMENTS.

Somaliland.

A REPORT prepared by Mr. H. B. Kittermaster, Secretary to the Administration, states that in 1922 1252 cases were admitted to hospital and there were 17,696 out-patients. These were treated for scurvy 18, ulcers 4196, tuberculosis 167, malaria 115, relapsing fever 92, small-pox 10, influenza 164, dysentery 74, syphilis 844, and gonorrhœa 313. The health of the European population was good. Two officials were invalided, one for dysentery and the other for chronic dyspepsia.

Straits Settlements.

These Settlements, comprising Singapore, Penang, and Malacca, with the dependencies of The Dindings, Cocos-Keeling Islands, and Christmas Island, have a total area of about 1600 square miles. Labuan was incorporated in the Straits Settlements in 1907; its area is 28·6 square miles. The population of Singapore, according to the census of 1921, was 451,912, of Penang 304,335, and of Malacca 153.522. The number of births and deaths registered during the year was 27,723 and 27,804 respectively. In Singapore the deaths exceeded the number of births by 1158, whereas in Penang, Malacca, and Labuan the births were more than the deaths. The crude birth-rate was 30·59 per 1000, against 32·57 in 1921; the decrease probably results from the slump in trade and employment. The percentage of males born was 52, females 48. The highest birth-rate in any nationality was 37·71 per 1000, against 32·57 in 1921, in both years Malay. The lowest was among Indians, 21·43. The infantile mortality (deaths of children under 1 year) was 207·52 per 1000 births, an increase on the previous year when it was 190·69 per 1000. Malacca shows the highest figure, 1128 infantile deaths amongst 4992 births, or 225·9 per 1000; this emphasises the need for more trained Malay midwives. The number of deaths from infantile convulsions, mostly due to tetanus, was 3146, against 3742 in 1921. The crude death-rate was 30·68, against 31·79 per 1000 in 1921; this is the second lowest on record. The highest racial death-rate for the year was 32·15 amongst Chinese, the lowest 9·04 amongst Europeans. The deaths from pneumonia were 1068, against 1230, and from influenza 234, against 237 in the previous year; it is to be borne in mind that Europeans if sick for any length of time usually leave Malaya. Beri-beri accounted for 1388 deaths, as against 1229 and 1026 in 1921 and 1920 respectively. Malaria and tuberculosis were responsible for 3977 and 2966 deaths respectively, against 4703 and 3258 in 1921. Deaths from fever unclassified were 3043, against 2367 in the previous year. Dysentery caused 1085 deaths and diarrhœa 458, against 1090 and 263 in 1921. There were 45 deaths from cerebro-spinal fever, 39 from plague, 2 from cholera, and 80 from small-pox.

THE GARB OF THE PHYSICIAN.

A HISTORICAL study of the garb of the physician in France was written some time ago by Dr. Cabanès, of Paris, and this study has now been extended to include the physician in other lands, as illustrated by contemporary drawings and paintings. The description of English physicians in "Le costume du médecin à l'étranger"[1] was compiled with the aid of Sir Anthony Bowlby, Dr. J. D. Rolleston, and others. Holbein reproduced several types of doctors during his residence at the Court of Henry VIII., such as the famous Dr. John Chambers, in fur collared robe, physician-in-ordinary to the King. Hogarth portrayed the doctors of his time with irony. He dealt as severely with physicians as with judges, advocates, lawyers, or churchmen, fleshing his mordant wit in the quackery of the one profession as he did in the incompetence of the other and in the ignorance of all. His famous picture of "Doctors with their Walking Sticks" is a masterpiece of irony, although a little far-fetched. In this picture the physician is clad in a long robe buttoned down in front or with lapels, a square-crowned hat or a flattened velvet cap, sporting a wig with many curls, and carrying the inseparable knob-headed stick. The physician was thus hardly to be distinguished from the townsman of the day. The dress of doctors of France and abroad is an expression of the same principle which underlies a similar psychology.

AN EARLY OBSERVATION OF CAISSON DISEASE.

THE late Deputy Inspector-General Archibald McKinley, R.N., who died on May 17th at Southsea, was the first to demonstrate, in 1900, at a post-mortem examination, the pathology of caisson disease, which had hitherto been very obscure. The case as given in the "Health of the Navy" Blue-book, 1900, p. 102, is as follows:—

"A man went down in a diving dress to $24\frac{1}{2}$ fathoms, remained down 40 minutes, and came up in 20 minutes, slowly, and was quite all right for eight or nine minutes when he complained of pain in the stomach, and collapsed, became cyanosed, and died in six or seven minutes. In the choroid plexus there were bubbles of air in the vessels, giving a beaded appearance. The veins of heart and mesentery looked similar and air came in a puff from the right heart when opened. He (McKinley) suggested gas had been absorbed by blood under pressure of $4\frac{1}{2}$ atmospheres and afterwards escaped as from soda-water, causing death from air embolism."

Dr. McKinley received his medical training at the Royal College of Surgeons in Ireland, where he qualified as licentiate in 1872, and the following year obtained the L.R.C.P.I. and L.M.

WALKING FOR HEALTH.

Dr. A. H. Doty, in a recently published little book entitled "Walking for Health" (New York: D. Appleton and Company, 1923, pp. 44, 2*s.*), emphasises the necessity for those engaged in sedentary occupations of taking a walk of from one to five miles in the open air every day. He points out that the exercise of walking steadily has a beneficial effect upon the circulation and may reduce the liability to arterio-sclerosis. The book is pleasantly written in a popular style.

A NEW ACOUSTIC AID FOR THE DEAF.

THE "Aurolaid" pattern of electric acoustic aid for the deaf is made on the same principles as other electric aids and is a well-constructed piece of apparatus. This pattern consists of two identical, or twin, instruments, one of which can be worn on each ear, and the transmitters can be placed in a small leather attaché case provided with openings at the back to transmit the sound. The receivers are particularly small and neat, are provided with a vulcanite projection to fix into the meatus and with a flexible metal hook to pass around the auricle, thus avoiding the use of a head-spring. Each transmitter is double and, having a hinge between the two parts, can be bent to stand on a table. The apparatus is small and light, the twins weighing 15 oz., each, but not 7 oz. as stated by the makers. We have tried it on a few cases of severe middle-ear deafness, and have found it powerful and effective; but there is a considerable amount of adventitious noise, and a certain amount of distortion of the voice, which we hope that the ingenuity of this old-established firm will be able to overcome.

The apparatus can be obtained from the makers, Messrs. F. Charles Rein and Son, 30, Charing Cross-road, London, W.C. The price of six guineas is a reasonable one.

FRAUDULENT BEGGING FROM MEDICAL MEN.

A MAN named William Stanley Reeves, alias William Stanley Bennett, has been committed at Peterborough on a charge of obtaining a cheque and money from medical men on false pretences. His fraud was based on the false statements that he was a physical training instructor to a boys' club and that the particular doctor on whom he called had been elected president of the club: he then asked for a subscription to meet a deficiency of funds. The man is 32 years of age, is 5 feet $7\frac{1}{2}$ inches high, has dark-brown hair and a dark complexion, and it is stated that he has had previous convictions at St. Albans, Devonport, Plymouth, Warminster, and Woking. We understand that the Chief Constable of Peterborough would be glad if any person who has been defrauded will give particulars of their complaint to the Chief Constable's Office, Peterborough. Their attendance as witnesses would not be required.

THE NURSING OF SURGICAL TUBERCULOSIS.

THE great advance being made in the treatment of children suffering from surgical tuberculosis, which advance is both curative and educational, has necessitated highly specialised nursing. Miss Janet P. Robertson, matron of the Lord Mayor Treloar's Hospital and College at Alton, has made a valuable contribution in this direction in a small book entitled "The Nursing of Surgical Tuberculosis in Children" (London: Scientific Press, pp. 88, 3*s.*). The book includes an outline of the nursing of the common forms of surgical tuberculosis; valuable information with reference to splints, diet, and education; and useful chapters on plaster work and sun treatment. The good work achieved at Lord Mayor Treloar's Hospital, Alton, is now well known, and it is a privilege to have, in such concise form, information directly based on the experience of those who have contributed so substantially to the success of this work. The last chapter on administration is especially useful.

Corrigendum.—In Prof. A. V. Hill's lecture on the Function of Hæmoglobin in the Body (THE LANCET, May 17th, p. 994, col. 1, line 15) the word "hæmochromogen" should read "hæmatoporphyrin."

SOME
Fundamental Factors
CONCERNED IN THE
SPREAD OF INFECTIOUS DISEASE.

A Paper read at the Congress of the Royal Institute of Public Health, held in Bordeaux on June 4th.

BY SHELDON F. DUDLEY, O.B.E., M.D. LOND., D.P.H., D.T.M.,
PROFESSOR OF CLINICAL PATHOLOGY, R.N. MEDICAL SCHOOL, GREENWICH.

IT has been my fortune during the past decade to have had exceptional opportunities for studying disease outbreaks in ships and schools, both as a clinician and a laboratory worker. I have therefore chosen for my subject some of those factors which govern the constantly changing balance between man and the microbes that depend on him. The laws that control the character of an infectious disease and regulate its distribution in time and space are of paramount importance to all medical officers, or indeed to any one, who is employed in trying to conserve the public health. The time at my disposal forces me to be somewhat brief and dogmatic; and I shall only discuss one or two aspects of the subject which I have had especial opportunities of studying.

Some of the evidence, experimental and otherwise, which will be used to support the theories I wish to bring forward has not yet been published in detail, but I hope it soon will be.

MICROBIC DISSEMINATION AND DROPLET INFECTION.

All organisms must arrange for their dispersal in space and time, or else cease to exist. In fact, an adequate means of dissemination is one of the biological hall-marks of a successful species. In the case of the disease-producing microbes and other dependent organisms which inhabit man, dissemination means the infection of fresh human hosts, often as cases of or carriers of disease. A parasite which fails to arrange the transport of its offspring to another host commits race suicide.

I am only going to discuss here one important method of dissemination which is used by microbic parasites—that is, "droplet infection." Flügge, in 1897, first drew attention to the fact that microbes could be transported over short distances in small droplets expelled in talking, coughing, or sneezing. A study of the experimental work since done on this subject leads to the following conclusions. Infection by means of droplets generally only takes place at very short distances, in spite of the fact that microbes can travel over 30 feet from their source of origin by this method. But at such distances the infected droplets are in very low concentration. As one would expect, the smaller the room the higher the concentration of infective droplets that can be produced in the air, other conditions being the same. Within half an hour of being released into the air, the vast majority of droplets settle out of it by force of their own weight. My own experiments confirm the above observations, but there are one or two other important points about the mechanism of droplet infection which up to the present do not seem to have attracted very much notice. These points may perhaps be most easily grasped if I describe one or two experiments among some I have lately been doing. Probably the most important thing to realise about the dispersion of droplets is that there are two distinct mechanisms. The first one is well-illustrated by this experiment. Two Petri dishes of agar medium 6 inches in diameter were fixed vertically upright 1 foot and 4 feet away from the mouth of a subject who had previously rinsed his mouth out with a suspension of *Bacillus prodigiosus*. The Petri dishes were coughed at, and then immediately covered. After incubation the near plate produced 28 red colonies of the index organism, whereas no red colonies appeared on the other Petri dish, which had been 4 feet away from the cough. This experiment illustrates the propulsive effect of the cough how it soon expends itself, but is able to immediately distribute a heavy concentration of droplets to a distance of 1 foot but unable to throw them as far as 4 feet.

In the next experiment, under ordinary conditions of ventilation, some of the organisms which had been released at one end of a room 40 feet long were able to infect Petri dishes which had been left exposed for one or two minutes at the other end of the room. At the time of the experiment there was no obvious draught, the doors and windows were all shut, and only one small ventilator, which during the experiment was acting as an exhaust, remained open. This ventilator caused an imperceptible current of air down the room, and the infected droplets were borne on this air current to the exposed Petri dishes. Under similar conditions, if the bacilli were released in the centre of the room, and the plates placed at each end, only the plates at the ventilator end were infected. That is to say, the droplets only spread with the wind. With the ventilator shut, the air currents were apparently lighter and more variable in direction, because in this case the microbe-laden droplets spread in both directions, but much more slowly.

These experiments show the two distinct mechanisms in the dispersion of droplets by talking, coughing, or sneezing. First, the cough produced a jet which is projected almost instantaneously to a distance of a foot or two when the air resistance quickly stops it. This jet contains all the heavier drops of mucus or saliva, and sometimes even obvious lumps of phlegm. The heavier particles practically drop to the ground at once, but the lighter droplets can float on the prevailing air currents for as long as half an hour, and be carried to comparatively great distances. Once pointed out, the mechanism of droplet infection is seen to be merely a matter of common sense. Any smoker can easily demonstrate the mechanism of air-borne infection for himself—blow out a mouthful of smoke, the smoke proceeds as a dense jet for two or three feet, when it is brought up rather suddenly by the resistance of the air; a localised cloud is then formed, which diffuses slowly through the room floating in the prevailing air currents. This cloud of smoke becomes less and less dense the further it gets away from the source of its origin. The short-range jet of heavy droplets is the usual means by which so-called "contact" infection is acquired. The best example of the practical application of this principle is seen in the "bed-isolation" treatment of infectious diseases. Owing to the impossibility of throwing a heavy dose of infective material more than a few feet it is possible to nurse two or three different infectious diseases in the same ward without any appreciable danger from cross-infection, provided the beds are far enough apart. The lighter droplets, it is true, may be borne considerable distances in the convection and diffusion currents of air, but, as will be seen later, are in such low concentration that they rarely are able to supply a dangerous dose of infectious material. This, at least, is the case with many diseases and under ordinary conditions of ventilation.

It might be argued that the above observations do not apply to the actual distributors of pathogenic organisms—namely, real cases and carriers—because a very high concentration of a harmless germ, *Bacillus prodigiosus*, was used as an index organism. However, bacteria-laden droplets are real things and can be actually caught and examined directly. Microscopic glass slides, if coughed at and stained, will show droplets of many sizes, containing leucocytes, epithelial cells, and in many instances, if produced by suitable subjects, will be seen to contain literally hundreds of organisms of various kinds. If instead of coughing at a slide a Petri dish of culture media is used instead, the same organisms as were to be seen on the slide will often grow, and it is interesting to note that what seem to be separate isolated colonies on the plates often prove on examination to be compound colonies containing two or more types of organism. For example, in one subject streptococci, Gram-negative diplococci, and diphtheroids could be seen in the directly-stained droplets. On a plate prepared from the same subject many compound, though apparently simple, colonies grew, some of which contained the same three organisms as were seen in the directly-stained droplets. Therefore a colony on a "coughed-at plate" marks the site where a droplet has fallen, and the droplet may have contained numerous bacteria of several kinds. Even a colony that appears to be a pure culture is unlikely to have arisen from an individual bacterial cell. Another piece of work by Teague [1] showed diphtheria bacilli could be disseminated by droplets. Forty-three diphtheria cases coughed at plates held in front of their mouths and in 28 instances diphtheria bacilli were recovered from the plates.

Perhaps the most impressive demonstration of the transport of microbes by air in droplets is an experiment that Prof. W. Bulloch informed me he often did years ago. After rinsing his mouth out with a suspension of *B. prodigiosus* and coughing, he was able to recover the same organism from the mouth-washings of a subject who was, at the time of coughing, 40 feet away from him.

Dosage and the Velocity of Infection.[2]

It is a common observation that some diseases are easier to catch than others—for instance, small-pox is more infectious than leprosy. The degree of infectiousness of a microbe may to some extent be an inherent property of its specific protoplasm, and it is possible that this character of infectivity may vary in different strains of the same species of microbe. On the other hand, apart from any difference in the quality of the infectious material, the quantity or dose of infectious material received must be of paramount importance in determining whether or not a microbe will be able to establish itself in the host species.

Webster,[3] as a result of his studies in mouse typhoid, considers the number or dose of bacilli to be the most important factor in deciding what type of illness the mouse contracts, and he does not think there is much evidence that the quality of infectivity, per se, varies to any marked degree in the same strain of bacilli under different conditions. Anyhow, animal experiments show that, in many infections, a large number of microbes are necessary before illness or death can be produced. For example, in diphtheria about 50,000,000 diphtheria bacilli are necessary to kill a guinea-pig. However, this dose may be much larger or smaller according to the strain of bacillus used.

Directly a quantity or dosage factor is admitted to a place of importance in microbial infections it becomes absolutely essential to introduce a time factor. For example, suppose 100 is the minimal number of organisms that will enable an infection to be produced in a certain individual; it immediately follows that any number less than this "minimal infective dose" will be rendered harmless by the defensive mechanisms of the recipient host.

Imagine in this case where 100 is the minimal infective dose that 50 microbes are received at one time, and another 50 at a later time, and so on; what will happen? If the intervals between these subinfective doses are long enough for one to be destroyed before a succeeding one is received, obviously in these circumstances no infection is possible. But suppose the intervals between the doses are not long enough for all of the 50 microbes in each dose to be rendered harmless before another dose is received, a certain number will be left over and added to the succeeding dose. And if the process continues and doses, each harmless in itself, go on being received at these short intervals, active organisms will steadily accumulate till they reach the minimal number or "critical dose" necessary to break down the primary defences of the individual and thus start a definite illness.

We are now in a position to combine dosage and time into a velocity and can enunciate the following principle. The velocity at which microbic infection is contracted is the resultant of two other velocities—namely, the velocity at which the defence mechanisms of the host can destroy microbes, and the velocity at which the host receives the microbes. Suppose a certain individual can deal with 50 bacteria per hour; unless he receives more than 50 of these organisms in an hour he can never be infected. Suppose that the "critical dose," which is the minimum number of bacteria necessary to produce infection, is 100. Then, if this individual receives 100 bacteria in a single dose, he immediately becomes infected, but if he receives more than 50 per hour but less than 150 per hour it must depend on how long he remains under the same conditions as to whether or not a critical dose can be accumulated. Suppose he receives 75 microbes per hour. At the end of the first hour there will still be 25 active microbes, since he can only deal with 50 per hour. During the second hour he receives 75 more microbes, to which must be added the 25 left over from the first hour; of this 100, 50 are destroyed, which still leaves 50 active microbes unaccounted for at the beginning of the third hour. Thus in this special instance microbes are accumulating at the rate of 25 per hour, which is the velocity of infection under these conditions. The "critical dose" was postulated as 100, so in this case the time necessary to acquire an infection would be 100 divided by 25—namely, four hours. Should the same man only remain three hours in the same environment he would only have acquired 75 active bacteria, which is 25 less than the number necessary for infection, and on leaving the bacterial environment his natural defences could account for these during the next hour and a half. In the above example, V the velocity of reception was 75; U the velocity of destruction was 50. The velocity of infection was V minus U—namely, 75 minus 50, that is—25. Let M represent the critical, or minimal infective, dose which was 100 in our example. Then if T is the time necessary to produce infection the whole principle relating time to dosage in the production of infection can be expressed as a "pseudo—mathematical equation: $T = \frac{M}{V - U}$. The time necessary to contract infection equals the minimal infective dose divided by the velocity of infection.

It must be understood this formula only envisages a principle which I am convinced is of great importance in understanding the spread of disease. No exact numbers can ever be given to the above letters which are all variables altering from minute to minute and which are bound to be different for each type of parasite and host. In a host possessing a high degree of resistance to infection, the velocity of destruction and the critical dose will both be of much greater magnitude than in an ordinary individual. The velocity of reception will vary with the distance and the character of the source of the microbes, which is generally a patient or a carrier. The atmospheric conditions, the ventilation, and size of the room also play a part in determining the velocity of reception in the case of those microbes which are disseminated by droplet infection.

An example of how the velocity of infection can explain certain phenomena will be given from the study of an epidemic of diphtheria and scarlet fever. In a school which contained both day boys and boarders there were over 300 infections among the 1000 residents; whereas there was not a single case of scarlet fever or diphtheria among the 100 day boys, who freely mixed with the boarders at play and in class. The chief, and practically only difference between the residents and day boys was the fact that the latter slept in their different homes while the former slept, a hundred or more together, in large dormitories.

The study of the incidence of scarlet fever and diphtheria cases and their spread in the school produced evidence that showed the disease spread chiefly from boy to boy in the dormitories; there was little evidence to show much infection was contracted at play, meals, or in the class rooms. It is the absence of any morbidity at all among the day boys that requires an explanation. A lower morbidity in the day boys than in the residents would have easily been explained by less time spent in the school, and therefore fewer opportunities of contact with the distributors of infectious material. This complete escape of the day boys is explained by supposing that the hour to hour and a half spent in the classroom, and shorter periods of still closer contact with carriers and early cases while at play, did not give the prevailing velocities of infection long enough time to produce illness. Any germs the day boys may have collected were easily accounted for on their returning home, or in other intervals of absence from the bacterial environment. On the other hand, the residents spent ten hours continuously in beds with a distance of 4½ feet between their centres, therefore a velocity of infection, which would have been innocuous in the hour or two spent at work or play, had sufficient time to infect during the ten hours spent in the sleeping quarters. In this school *time* was the main factor which controlled the epidemic, and which accounted for a 30 per cent. morbidity in one group of boys against a complete absence of morbidity in another group.

The principle of velocity of infection may be a little difficult to grasp at first, or, rather, the necessity for the introduction of the time factor not fully realised. A further hypothetical example may make things clearer. With certain individuals and in certain types of microbic disease, of course, not all, long continuous stays in an infectious neighbourhood may be more dangerous than many shorter periods spent in the same or an even more infectious environment. Take, for example, a man who travels to his office every day with a friend who is a disease carrier. Every day they spend half an hour in close proximity to each other in the crowded tube, but the man never gets infected from his friend. One day these two men go to a theatre together and sit out a three-hour performance. The man now contracts the disease his friend carries. The velocity of infection was not high enough to cause illness in the half hour spent in the tube, but was great enough to do so in a period six times as long, spent in the theatre. This hypothetical case is purposely chosen as it has been stated, on what grounds I do not know, that disease is more often contracted in places of amusement than in trains and public vehicles; yet, in the aggregate, most people spend more time in public vehicles than at entertainments, and if disease is really more frequently contracted in the latter than in the former, an explanation is easily furnished by the theory of the velocity of infection.

HOST RESISTANCE AND EPIDEMIC IMMUNITY.[2]

In the previous paragraphs mention has been made of the host's defence mechanisms to microbic attack, and to avoid complicating the discussion, up to the present I have treated these mechanisms as if they were a constant factor. Of course, this is not so, as infection depends as much on the power of resistance of the host as on the dosage and infectivity of the microbe. In fact, I think most bacteriologists would say the host's power of resistance was a more important factor than either dosage or infectivity in acquiring a disease.

A population can loosely be divided into susceptible and immune persons. Although this is a convenient convention, yet it is not logically correct. There are few individuals who are completely susceptible, as literally this would imply that a single microbe was sufficient to initiate an illness in them. On the other hand, many of those who are ordinarily immune may, under special conditions, succumb to a sufficiently massive dose of infectious material. Immune and susceptible are, however, convenient terms, provided it is realised that they stand for a very high and very low degree of resistance to microbic infection. The division of the population into two distinct groups may in fact be nearer to the truth than appears at first sight, because there is some reason to believe that, in the majority of people, specific resistance to disease is either high or low—intermediate grades of resistance not being so common. The degree of resistance, even of an individual, is by no means constant and may show periodical variations under different conditions. McCarrison[4] has shown that vitamin deficiency may permit auto-infection by a microbe, which had formerly been living in a state of balance with its host, before the faulty diet was instituted; as he puts it, "the carrier becomes a patient." Thus faulty nutrition can lower resistance. Further examples are the effect of fatigue and chill in lowering resistance to influenza and pneumonia.

The production of an increase of specific resistance to a specific microbe will now be considered. It is one of the oldest observations in medicine that in many diseases one attack confers immunity to a subsequent attack of the same nature. This immunity is very much greater and more lasting in some diseases than in others; for instance, contrast mumps and influenza in this respect. Can an immunity of this specific nature be acquired without actually suffering any symptoms of ill-health? At the present day it is an acknowledged fact that resistance to typhoid fever can be increased by injecting the causative bacillus under the skin, or even by swallowing it. This fact is made use of in the services to control enteric disease by the routine use of prophylactic vaccines.

In a preceding section it was pointed out that in certain environments an individual must often be receiving small doses of microbes, which he is able to destroy without getting ill, provided they are not received too often or too quickly, or, in other words, provided the velocity of infection is small enough. The specific proteins of the microbes in these subinfective doses are absorbed or may be carried by phagocytic cells into the host's tissues, where there is no reason why they should not stimulate the production of antibodies just as efficiently as microbes injected with a syringe. This process is Nature's method of vaccination and may account for much acquired immunity to infection or disease.

This theory of auto-vaccination, as a cause of immunity, receives powerful confirmation from a quite independent source. Digby,[5] in some work that deserves far more attention than it has yet received, produces morphological and embryological evidence to show that the submucous lymphoid tissues (which include the tonsils, Peyer's patches, and the appendix), are not mere vestigial survivals and therefore useless to all animals, except surgeons and pathologists, but that they are organs with a definite function. This function is the collection and absorption of samples of all the microbes in their neighbourhood. Wandering cells from these lymphoid tissues carry the microbes back into the body for the express purpose of stimulating specific defence mechanisms against a further invasion. The very frequency with which these organs suffer local microbic invasion, such as occurs in tonsillitis, appendicitis, and enteric fever, merely indicates that they have fallen victims to their duty by accumulating an overdose of the pathogenic bacteria in their environment. As a result of his researches Digby evolved this theory of natural auto-vaccination, which was independently arrived at by myself as the result of the observations on diphtheria shortly to be referred to. It is now easy to realise that ordinary prophylactic vaccination may only be an imitation of an adaptive defence mechanism, which host species have evolved as their answer to the attacks of parasitic microbes. Walcott[6] has shown that the bacteria were present in pre-Cambrian times, at least 50,000,000 years ago, so that the species in existence to-day are only those who survived in the age-long struggle for existence with the bacterial environment.

Although this theory of auto-vaccination may not be acceptable to some minds, yet that a population can gain a large increase in resistance to diphtheria in the absence of all symptoms of illness, and even when the community is free from cases of clinical diphtheria, is a proved fact. In diphtheria, by the use of the Schick test, it is possible to distinguish the immune from the susceptible. As possibly some may be unfamiliar with the Schick test, the rationale of the test had better be explained The Schick reaction is performed by injecting a minute dose of diphtheria toxin into the skin. If the subject is a negative reactor no redness appears at the site of injection because the injected toxin is neutralised by the diphtheria antitoxin which is present in the blood of those immune to diphtheria. In subjects with a low degree of resistance to diphtheria the injection of the toxin causes an inflamed red patch, because there is no, or insufficient, circulating antitoxin to neutralise the diphtheria toxin which has been injected. For practical purposes Schick positive reactors are susceptible, and Schick negative reactors are immune, to diphtheria.

The results of the Schick tests on the boys of a school showed that during a diphtheria epidemic the majority of the susceptible individuals in this school population acquired diphtheria antitoxin in their blood and thus became immune without suffering from any illness. Further than this, bacteriological investigations showed that when the epidemic had subsided there followed a still greater epidemic of carriers of virulent diphtheria bacilli. During the two years following this school outbreak of diphtheria some 250 "Schick-positive"—that is, presumably susceptible—boys were introduced into this diphtherial environment and about half these boys subsequently became "Schick-negative"—that is to say, they were practically incapable of contracting clinical diphtheria. This immunity was acquired without the boys being ill or, in most cases, without ever having had a chance of contact with a case of diphtheria.

Now this fact, for it is a fact whatever the explanation may be, demonstrates a factor in epidemiology whose importance cannot be exaggerated—namely, that it is possible, in the absence of all obvious illness, for a community as a whole to increase its degree of resistance to a potentially pathogenic parasite. More often than is realised unseen epidemics of "disease carriers" are occurring sometimes without any cases with symptoms to attract attention to them. In many infections undetected carriers must be much more common than cases showing symptoms. In epidemic meningitis, for example, there must be at least 100 carriers to every case of meningitis. In the school which has been used so frequently for examples there were at least ten carriers to every case of clinical diphtheria. These observations should convince us that the carrier state of infection is, under certain conditions, more natural or normal than the definite disease. In addition, under certain conditions, as yet not completely determined, epidemics of carriers can occur without any cases of ill-health to attract attention to them. These unseen epidemics of carriers, in the way just described, are capable of increasing the resistance of the population as a whole to the disease that the carried microbe sometimes causes. In the school under consideration, without the employment of bacteriological tests on healthy boys, no one could have guessed that with a virulent carrier-rate sometimes as high as 10 per cent., and with a complete absence of diphtheria morbidity, susceptible boys were becoming immune to diphtheria at an average rate of about 10 per 100 per month. The increase of resistance to a specific disease parasite thus acquired by a population may conveniently be termed "epidemic immunity." Notice that "epidemics of immunisation" may or may not be accompanied by epidemics of disease.

At present diphtheria is the only epidemic disease which produces an easily identified antitoxin in the blood of the immune, and therefore is the easiest infection to study as regards the proportion of immune to susceptible in samples of the population. However, though the evidence cannot be so direct, many observations indicate that other infections obey the same biological laws. There is no time to discuss this question much further, but in the case of influenza in a school where the morbidity was 25 per cent., the incidence of disease was inversely proportional to the length of residence in the school. This indicates that those groups of boys who had spent the greatest time in the school environment had acquired an increased resistance to attack by the causative organisms of influenza, even if there was no history of their ever having had influenza. Again, during the influenza epidemic there were two obvious waves of the disease in His Majesty's Fleet,[7] a mild first wave followed by a deadly second one. Some ships escaped the first wave; this was a doubtful blessing, as the second wave struck them with more than double the force it expended on those ships which had had the immunising experience of the first wave. In the latter ships the morbidity and mortality was less than half that in the former.

Another example of immunity in absence of symptoms in seen is the case of tuberculosis. During the late war the incidence and severity of tuberculosis was much greater in the coloured native troops, recruited from regions where tubercle is practically unknown, than among British soldiers, all of whom had probably acquired some resistance to the tubercle bacillus, because in England everyone must frequently inhale subinfective doses of tubercle bacilli.

To summarise, the *fact* is this, that many people can increase their resistance to a specific disease without suffering from it. The *theory* used to explain this fact is that in a bacterial environment subinfective doses of organisms are frequently received. These doses are absorbed by the tissues and stimulate the production of antibodies in a way similar to the ordinary injection of a bacterial vaccine. This theory, which may or may not be acceptable, certainly deserves very careful examination in view of the importance of "epidemic immunity."

The Variation of Parasitic Virulence.

The last subject I will deal with is that of parasitic virulence as an adaptable rather than a specific character. For the present purpose virulence can be defined as the extent to which a parasite can injure the host.

The question as to what constitutes the difference between a species and a variety, though of fascinating interest, is too big to treat at length here. Darwin himself admitted species was a convenient conception but incapable of a hard-and-fast definition. A recent authority, Prof. A. Dendy,[8] describes a species thus: "A species is a group of individuals, closely resembling one another, owing their descent from a common ancestor, which has become more or less sharply separated from all other coexisting species by the disappearance of intermediate forms." In this definition the phrase "closely resembling" leaves it to the individual biologist to decide for himself how closely two organisms must resemble each other in order to be two varieties of one species, or to be two distinct species. In this discussion a species will mean a group of parasites which will remain constant in certain characters over the period of human observation. In this respect a meningococcus is a distinct species from a staphylococcus, as even if in the past both had a common ancestor, the intermediate forms have now disappeared. Varieties, on the other hand, have quite recently descended from a common ancestor, and under suitable external stimuli from the environment can revert to the "type species" or change the one into the other within a reasonably short time. Any variations which may take place in pathogenicity or virulence are especially relevant to our subject, and if adaptations they must chiefly occur in the natural habitat of the parasite—to wit, man himself, where, owing to the great technical difficulties, it can rarely be possible to furnish direct proof of their occurrence and still more so of their non-occurrence. It does not seem reasonable, therefore, to consider that virulence is, in all cases, a permanent specific character; still more is this so when we find that in nearly every instance the natural habitat of a pathogenic microbe also supports organisms which are similar in all respects to the disease germ except that they lack virulence. Serological characters, on which the bacteriologist rightly depends so much in identifying disease organisms, are obviously the result of contact between host and parasite. Serological characters are also correlated to some extent with virulence, and nowadays many authorities do not consider the serological individuality of otherwise similar organisms is sufficiently constant to establish a species. For example, four serological varieties of meningococci are usually described, but they are probably only fluctuations within the species, and if the proper stimuli were known, and could be applied, doubtless one type could change into another.

Numerous observations show that species vary directly in response to changes in their surroundings. These fluctuations or adapted variations are often of a quantitative rather than of a qualitative nature. For example, as was seen in the previous section, the species man can be divided into two varieties, the one with a high, the other with a low power of resisting the attack of the diphtheria bacillus, and in this case the resistant variety of the human species is probably an adaptation to an environment containing diphtheria bacilli. The present tendency, I think, favours changes in host resistance rather than variable microbic virulence as the chief factor in the causation of periodic epidemics or changes in the type of infection. On the other hand, the founder of modern bacteriology, Pasteur, considered the chief determining factor was virulence. In some cases pathogenicity may be caused by low host resistance and in others by high parasitic virulence, but most illnesses are probably due to a combination of both these factors.

It seems logical to expect adaptive variations to occur as much in the parasite as the host, especially in the case of the bacteria, who owe their prominent position in the living world to their great plasticity, which has enabled the bacteria to colonise every kind of environment. Superficially virulence appears to be a character that increases the fitness of the organism to live in its environment, and therefore some writers actually refer to loss of virulence as degeneration. Under certain conditions, in a rapidly changing environment, and when susceptible hosts are numerous, increased virulence may be an advantage and a temporary adaptation to meet special circumstances. But in general marked virulence will ultimately become a handicap in three ways. First, by the destruction of susceptible hosts the parasite destroys its own environment. Secondly, a rapid severe illness limits the movement of the host and at the same time limits the distribution in time and space of the causative parasite. Thirdly, virulence may stimulate so much resistance on the part of the host that the parasite possessing it is destroyed in cases where a less virulent strain might have been tolerated. Therefore a permanently virulent parasite will be at a great disadvantage in the struggle for existence, compared with one that can vary virulence to fit different environments. On the whole, virulence shows a lack of adaptation to environment and therefore tends to be eliminated by natural selection.

In many bacterial species virulence, estimated as the power of killing experimental animals, is easily altered in the laboratory. Only two interesting instances of this need be mentioned. Griffiths [9] was able to greatly attenuate the virulence of pneumococci by growing them in a medium containing the homologous antibodies; in other words, by keeping this parasite in contact with the serum of an immune host. The reverse experiment of raising pneumococcal virulence was achieved by Felton and Dougherty,[10] who repeatedly transferred large numbers of the cocci at the time of their maximum vitality into a fresh bulk of nutrient medium and thus kept them continually in an environment favourable for rapid multiplication. Under these conditions the organisms' virulence for mice increased over a million-fold. Just as vaccine prophylaxis is most likely only an imitation of the natural process of acquiring immunity, so it is not improbable that the above experiments also imitate the methods of altering virulence that actually happen in nature. Some observations have been obtained that seem to support such a theory. Towards the end of the aforementioned diphtheria epidemic, though the carrier-rate for virulent diphtheria bacilli was always less than 5 per cent., and a series of Schick tests showed the number of susceptible boys to be only 14 per cent., yet under these conditions membranous diphtheria was still able to spread in the school, as is shown by the fact that 30 cases subsequently occurred. Two years later further Schick tests and throat swabs revealed that in some samples the carrier-rate for virulent diphtheria bacilli was as high as 10 per cent., whereas those boys who gave Schick-positive reactions had increased to 24 per cent. It must be mentioned that the increase in susceptibility of this population was due to the introduction of Schick-positive new boys at the rate of about 50 per term. The boys once immune did not become susceptible again during the period of observation. Thus, after the complete cessation of a diphtheria epidemic, in a population where all other conditions remained unchanged, except that the number of susceptible hosts and the number of carriers of virulent bacilli both greatly exceeded the numbers that existed during the time when clinical diphtheria was still prevalent, no case of the disease had been seen for many months.

The explanation suggested for these observations is as follows. Susceptible boys must have been three or four times as numerous just before the onset of the diphtheria epidemic as during its final phase; therefore the diphtheria bacillus in its passage from boy to boy met conditions, where its activity was unchecked by host resistance, much more frequently at the beginning than at the end of the epidemic. Such conditions imitate to a great extent the method of raising pneumococcal virulence previously mentioned and favour rapid multiplication and maintenance of virulence. Towards the end of the diphtheria epidemic the ratio of immune to susceptible hosts increased up to 6 to 1, so that the diphtheria bacilli had many more opportunities of infecting immune boys as carriers than of causing cases in the few remaining susceptible boys. In these circumstances the greater amount of contact with immune hosts gradually caused a loss of pathogenicity, just as in Griffiths's experiments the pneumococcus lost its virulence in presence of serum from a specifically immune animal. With the loss of pathogenicity the diphtheria bacillus became a less efficient immunising agent and permitted the aggregate susceptibility of the school to increase—a speculation which receives support from laboratory observations on the relative immunising power of virulent and avirulent strains of the same organism. If such a process did take place it may have been aided by artificial selection of the less virulent organisms in this way. All those boys who were infected with diphtheria bacilli and had symptoms were isolated in hospital till free from the specific bacilli, whereas a very small proportion of the total number of symptomless carriers were detected and isolated. Therefore if some strains of the bacillus had a greater tendency to produce cases rather than carriers they got less chance of spreading than other strains, who may have tended to produce carriers rather than cases of diphtheria. A recent series of Schick tests have shown that at the present time, in spite of the prevalence of virulent carriers, the immunity of the population has passed its maximum and is on the decline. The susceptibility, or rather the number of Schick-positive boys in the school, is actually greater now than it was when diphtheria was still capable of spreading. It would be interesting to see what would happen if things were left alone—Will all the carriers disappear, or some persist and, as the number of susceptibles increase, regain the power of causing membranous diphtheria, or must new virulent strains be introduced from another environment before a fresh outbreak of diphtheria can occur? The condition of affairs in the school is such now that it seems unjustifiable not to anticipate a fresh outbreak of diphtheria by protecting the Schick-positive boys with toxin-antitoxin mixture. Unfortunately, if this is done it prevents watching the progress of the diphtheria cycle up to the onset of a fresh epidemic. In other infections besides diphtheria the proportion of those with high, to those with low, resistance to attack may be an important factor in determining whether disease will spread or not.

Topley and Wilson,[11] in their experimental epidemics among mice, found that according as the proportion of mice protected by vaccination was large or small, the mouse typhoid bacillus would or would not spread easily among both the protected and non-protected individuals of the mouse population. Topley rightly emphasises the difference between individual immunity and the immunity of a population as a whole—"herd immunity" as he aptly terms it. Whether "herd immunity" is greater if all the population have a moderate degree of resistance or if some are very resistant and some susceptible is an important problem that yet requires an answer.

According to the thesis that I have been trying to develop the degree of herd immunity determines ultimately the disease-producing power of the biological agents of illness. In influenza, for example, there is little evidence of any lasting immunity conferred by a previous attack, yet naval experience showed that the disease spread less easily and was less malignant in a population that had recently experienced a previous epidemic. That is to say, the degree of "herd immunity" had certainly been increased, even though little difference could be noted as regards individual immunity.

Returning to our main theme of virulence as an adaptive variation, it must be admitted that one of the great objections to accepting altered virulence as a factor in epidemic periodicity, anyhow in the case of diphtheria, is that no difference (worth mentioning here) could be detected in the killing power for guinea-pigs, between bacilli isolated from membranous throats of the epidemic cases and those obtained from carriers more than a year later. To my mind this is not an insuperable objection. The balance between host and parasite is delicate. Parasites when transferred to hosts they do not normally inhabit sometimes exhibit marked and sudden variations, and general biological considerations rather incline one to expect that a recently acquired functional and negative quality, such as loss in the degree of virulence to the specific host, might be wiped out immediately on transferring the parasites to a non-specific host such as the guinea-pig. However, it has to be confessed this speculation is rather crushed by Webster's[12] experiments with mouse typhoid epidemics. This observer was unable to find any alteration of the killing power of the mouse typhoid bacillus when the conditions of experiment were varied, and in this case the same host was used both for the production of the epidemics and for measuring the virulence of the parasite. Should, however, virulence be used in the sense of power of injury to the hosts, rather than the power of killing an animal with a small single dose of microbes, it is quite easy to imagine possibilities where, using the former definition, virulence may be low, while at the same time virulence in the latter sense may be high. For instance, suppose infectivity, per se, decreases—a velocity of infection that formerly was sufficient to cause cases may now only be suitable for the production of carriers; or again, some strains of the same parasite on reaching the mucous membrane may multiply more superficially and slowly than others and permit the host to gain immunity in time to prevent symptoms. These pure speculations are merely introduced to show the complexity of the subject, and that the fact of not being able to detect variation in killing power of a parasite is no argument against some change having occurred in its power of producing disease. The evidence taken as a whole, in my opinion, justifies the following tentative hypothesis.

The reaction of the parasite to increase in host resistance is decrease in virulence. The reaction of the host to parasitic virulence is increase in resistance.

Should this hypothesis be true one would expect that, in a more or less stabilised environment, given time, a position of equilibrium would be reached between the attacking power of the parasite and the defensive power of the host. And in wild life, undisturbed by man, such is generally the case. For example, the wild game of Africa tolerate, without any apparent harm, the same trypanosomes that create havoc among man's domestic animals. In other cases the struggle to attain mutual adaptation by host and parasite, not the struggle between host and parasite, which is another thing altogether, may proceed even further than tolerance and succeed in producing true symbiosis, in which state one partner cannot live its full natural life without the other. A good recently-described example of symbiosis is that of the wood-eating termites, which are inhabited by intestinal protozoa without whose help the termites are unable to digest the wood.[13] In wild animals the struggle for existence is so keen among their offspring that any degree of pathogenicity on the part of a parasite will act as a severe check on the survival of those individuals affected. Sick animals, in general, are soon eliminated, and with them their virulent parasites.

Man, owing to the rapidity with which he has evolved the most efficient, even if yet far from perfect, adaptive mechanism intelligence, is the only host animal which steadily increases in numbers, and his parasites and domestic animals therefore share the increase with him. Man for ever interferes with the environment and mixes up the living conditions of himself and other organisms. By these means the balance between himself and his parasites is continually upset. The penalty for this upset is disease and epidemics, which are due to the parasites or the hosts not being able to adjust themselves quickly enough to the new conditions in their environment. Man, with his domestic animals and plants, though no more highly parasitised than many wild animals, yet in comparison to the latter almost monopolises parasitic disease.

Seventeen years ago Sir Ray Lankester[14] drew attention to this important, though somewhat neglected, fact, and I cannot do better than close this paper by quoting his words: "It is a remarkable thing—which possibly may be less generally true than our present knowledge seems to suggest—that the adjustment of organisms to their surroundings is so severely complete in Nature apart from Man, that diseases are unknown as constant and normal phenomena under those conditions. It is no doubt difficult to investigate this matter, since the presence of Man as an observer itself implies human intervention. But it seems to be a legitimate view that every disease to which animals (and probably plants also) are liable, excepting as a transient and very exceptional occurrence, is due to Man's interference."

SOME CLINICAL OBSERVATIONS ON
HELIOTHERAPY IN PULMONARY TUBERCULOSIS.

By BERNARD HUDSON, M.D. Camb.,
CHIEF MEDICAL OFFICER OF THE ENGLISH SANATORIUM, MONTANA;
AND
LEONARD HILL, M.B. Lond., F.R.S.,
DIRECTOR OF THE DEPARTMENT OF APPLIED PHYSIOLOGY, NATIONAL INSTITUTE OF MEDICAL RESEARCH.

(*With Illustrations on Special Plate.*)

THE sun-cure is now, thanks to the work of Bernhard and Rollier in Switzerland and Gauvain in England, generally admitted to be the most satisfactory method of treating the large majority of cases of localised or surgical tuberculosis—i.e., tuberculosis of the bones, joints, glands, and serous membranes. On the other hand, the sun treatment of pulmonary tuberculosis has fallen into disrepute and is generally considered dangerous by experienced medical officers at sanatoria. This is because sun treatment has, in many cases in the past, been tried on pulmonary cases in sun-boxes open only to the south or under glass, where a greenhouse effect has been produced, and because febrile cases have been submitted to such conditions which overheat in place of cooling the body. Moreover, a febrile case is fighting against active disease. Products of tissue destruction produced by the bacterial invasion of his tissues are being absorbed and his immunising power is being excited thereby. What he at the moment lacks is sufficient natural response. To sunburn him and throw extra products of tissue destruction into his blood is then wrong. His immunising powers are already over-taxed and cannot be further aroused. He needs, if only such could be had, an active anti-tuberculous serum taken from an animal immunised against the tubercle bacilli and in open cases against the other bacilli which produce secondary infection of the lung. People afflicted with pulmonary tuberculosis have been told, and are sometimes still told, to go to the south of France, the Swiss Alps, or some other sunny part of the world, and to sit about there in the sun, and they will soon be all right again. They take such advice, often with disastrous results. It must be recognised that indiscriminate and uncontrolled use of the sun in pulmonary tuberculosis is fraught with danger and must be vetoed. If applied wrongly and to the wrong type of case, sun treatment may set up flaming activity in a lung where the disease was, perhaps, only smouldering, and would have settled down under ordinary climatic and hygienic treatment.

Method of Treatment.

The point, then, is first to select those cases likely to be benefited by a course of heliotherapy, and, secondly, to endeavour to control the dosage and application of the treatment in each instance. First of all, it should be clearly recognised that it is not a hot sun which is required, but pleasantly warm sun-light and cool air. The treatment should not be carried out in an enclosed space, which is liable to become stuffy and hot, but should be done, as far as possible, in the open, with cool fresh air circulating freely around the patient.

The cool, dry air of the Swiss Alps in winter is one of the most beneficial factors in the proper application of the sun treatment in cases of pulmonary tuberculosis. The patients can be exposed with a loin cloth on or in a thin bathing costume on an open roof with their lounge chairs placed on the snow; the winter Alpine sun will gratefully warm them while they turn now their front and now their back to it. At the same time their metabolism will be stimulated by the cool air, and they will breathe cool dry air which enhances the flow of blood lymph and secretion in and through the respiratory membrane. The cool air, too, will moderate the action of the sun-rays on the skin. This method has been tried by us with good effect and has proved a valuable supplement to general treatment. We have designed shelters on the roof of the sanatorium with walls just high enough to give privacy and open to the sky. It is in the winter, when the snow has fallen, that the ultra-violet rays of the sun are least strong, and the cooling power of the air most in evidence, and it is in the winter, therefore, when the best results from this gentle moderated heliotherapy are to be expected. The winter sun is warm enough and even too warm sometimes at midday. On the other hand, the summer sun is very powerful round about midday. It must be used in the cool early morning hours when the sun is low in the heavens and its rays mostly absorbed by the atmosphere.

Types of Disease Amenable to Heliotherapy.

Heliotherapy may be tried in cases of tuberculosis of the lungs, where the disease is of the localised, single-focus type, thereby approximating in character to surgical tuberculosis. In cases where there is no fever and in which the activity of the disease has become arrested, but which are "sticking" and still have sputum containing tubercle bacilli, much benefit may be derived from such a course of sun-baths; the healing process is stimulated and the sputum and spitting of tubercle bacilli may cease.

Where the disease is of the scattered type, and especially where there is a liability to fever, either periodical or continuous, sun-bathing is dangerous and should not be attempted. Cases which easily auto-inoculate themselves and those who are prone to hæmoptysis should avoid exposure to the sun, but such cases are benefited by exposure to the cool air and ultra-violet radiation of the sky. From exposure to the sun, on the other hand, good results have been obtained in those instances where the disease is of the pleural type, with much thickening of the pleura and contraction of the chest; the thickening and adhesions are absorbed and cleared up, the lung expands and functions again, and there is a great general improvement in health. Another type which does well is the bronchial asthmatic.

As a general rule, it may be stated that where there is smouldering activity of the tuberculous process, as evidenced by fever, a tendency to auto-inoculate on exertion, hæmoptyses and other signs and symptoms of activity, then sun-bathing must be left alone, and the ordinary treatment of rest and open air carried out. Sun-bathing may be used as an additional stimulus to a case which is becoming cured, but in which progress is slow.

Sun-bathing consists in becoming gradually accustomed to withstand the rays of the sun, and should be commenced slowly, and increased regularly according to the needs of the patient. The head and neck should be kept covered. Sun-burning should be avoided, slight erythema followed by pigmentation, not burning, being what is required. When once pigmented and well on the road to cure the patient can stand more and more exposure to the sun. If the patient becomes fatigued, sweats much, or has a definite febrile reaction, the time of exposure to the sun must be cut down. Dark-haired people become accustomed more easily than fair ones to the sun's rays; in fact, some fair and red-haired people find it impossible to undertake a course of sun-baths. Toleration largely depends upon the amount of pigmentation that occurs, but the whole procedure, especially in pulmonary cases, should be a very tentative one, and most carefully controlled and watched. While much good may be done by sun treatment, this, if carried out wrongly, may cause a great deal of harm.

We are indebted to Mr. P. G. Sutton, radiographer at the English Sanatorium at Montana, for the photographs.

THE
MORBID ANATOMY AND PATHOLOGY OF SPRUE,

AND THEIR BEARING UPON ÆTIOLOGY.

By PHILIP MANSON-BAHR, D.S.O., M.D. Camb., F.R.C.P. Lond.,
PHYSICIAN TO THE HOSPITAL FOR TROPICAL DISEASES AND ALBERT DOCK HOSPITAL; LECTURER, LONDON SCHOOL OF TROPICAL MEDICINE.

(*With Illustrations on Special Plate.*)

One of the outstanding problems in tropical medicine at the present day is the true pathology and ætiology of sprue. All attempts up to the present to isolate a specific agent or organism have failed, nor has any really clear idea of the true pathology of this mysterious disease been formulated. This is a question of primary importance, for sprue is a widespread tropical disease, and in certain endemic areas, as in India and Ceylon, the number of sprue cases amongst European residents appears to be much greater than was formerly the case.

The *geographical distribution* of sprue has peculiarities which may have a very distinct bearing on its ætiology. Sprue is common in the Eastern Tropics as well as in South America, Southern United States, and North Australia. On the other hand, as has been remarked, but not, I think, sufficiently emphasised, sprue is entirely absent from Tropical Africa. Another point of prime importance is the predilection of the disease, in endemic areas, for the European in preference to the light or dark-skinned Asiatic.

Relation to Pernicious Anæmia.—A third point is the close clinical resemblance of some cases of pernicious anæmia to sprue, especially as regards their onset.

Pathology of Sprue.

Existing accounts of the morbid anatomy and pathology of sprue are very meagre. Much of the older literature treats of naked-eye changes in the intestines and organs which are obviously the result of post-mortem decomposition. It has been realised for some time that the true pathology of sprue cannot be based upon the appearances of cases dying of atrophy after a wasting illness prolonged over many years. The post-mortem appearances seen in these latter cases are the result of long starvation, and probably the early essential lesions of the disease have long since disappeared.

Emphasis has mostly been laid upon the marked attenuation of the small intestine, and the complete stripping of the mucous membrane. From time to time the liver, on account of the remarkable wasting this organ undergoes, and the pancreas, on account of the fibrotic changes observed, have been incriminated. But clinical observations lend no support to these views. On clinical grounds one is at least justified in surmising that the primary lesions are in the small intestine, and that the well-known ulcerations of the mouth and tongue are of a similar nature. In order to ascertain whether this is true it is necessary to examine at autopsy early and rapidly fatal cases of sprue. I have always been of the opinion that in early cases only will the true ætiological cause be discovered.

We have in bacillary dysentery an almost analogous case. We know that in this disease the appearance of the intestines in the chronic stage bears no resemblance to the acute necrotic, congested gut of the early infection, so that it would be impossible, without extensive experience, to say that the one was the outcome of the other. We further know that, as fibrotic and atrophic changes in the gut walls take place, so the ætiological cause—the dysentery bacillus—entirely disappears. So may it be in sprue.

Evidence is now accumulating that the essential primary lesion of sprue is an ulceration of the small intestine, chiefly affecting the lower end of the ileum. It is possible that in the mild cases the ulceration is superficial, leading merely to a catarrhal state of the mucosa, while in more serious cases the ulceration may be more extensive and involve the submucous tissue of the gut, and may, on occasions, perforate the gut wall and lead to general peritonitis and death, as in the two instances cited below.

Previous Cases.—Faber[1] in 1904, and Justi[2] in 1913, have published accounts of carefully conducted autopsies, in which a specific ulceration of the small gut was found, together with widespread destruction of the villi. Fischer and von Hecker[3] in 1922 published a study of a case dying of acute sprue, in which small linseed-shaped ulcers were present in the mucosa of the lower jejunum and ileum. In the cæcum numerous attenuated patches were present. No micro-organisms were demonstrable in the ulcers, nor could yeast cells be cultured from the lesions. In the bowel wall a diffuse hæmochromatosis, due to lipofuscin, was present. These investigators consider the ulceration of the bowel as specific of the disease.

Two Cases Described.

Within the last three and a half years I have had the somewhat exceptional opportunity of observing two rapidly fatal cases of sprue, and of making complete investigations with both of them.

Case 1.—An ex-soldier, aged 40, who had served with the Yeomanry in Salonica, Palestine, and Syria. This is the first case of this disease to be recorded from those countries. A year after demobilisation, in the early part of 1920, diarrhœa commenced; this was of the usual type—i.e., white, frothy, liquid stools passed in the early hours of the morning, together with progressive emaciation. The tongue and mouth symptoms appear never to have been well marked; the patient complained mostly of great sensitiveness of the mucous membrane of the lower lip, the tip and sides of the tongue. When first seen on 7/9/20, the patient was in a very emaciated condition, his voice was husky, the skin was dried, the abdomen was distended with gas, the liver dullness was much reduced, being barely perceptible to percussion.

He was admitted to hospital on Sept. 9th, and was placed upon purely milk diet. The stools then rapidly assumed typical sprue-like characters, being semi-solid, large, white, and greasy. In spite of the milk treatment, the patient continued to lose weight and to suffer from acute indigestion and flatulence. His weight, which was normally 12 stone, fell to under 7. Various changes of diet were tried, without any ascertainable effect. At the beginning of October dark patches appeared on the tips of both toes, which resembled incipient gangrene. Subsequently he complained of great pain in the right iliac fossa, and on several occasions vomited large amounts of undigested food. On Nov. 25th there was little doubt that general peritonitis had set in; an exploratory laparotomy was therefore performed, and general plastic peritonitis was found present throughout the whole abdomen, but no perforation could be located. Death occurred two days later. The blood pressure, which was systematically taken, was observed to fall from 120 mm. Hg systolic, till it reached 90 mm. Hg. The gastric juice contained no free hydrochloric acid. The blood examination showed a slight degree of anæmia, the hæmoglobin being 90 per cent., the red cells 4 million. Little assistance was obtained from sigmoidoscopic examination, which showed a diaphanous condition of the lower bowel and superficial reddening of the mucous membrane.

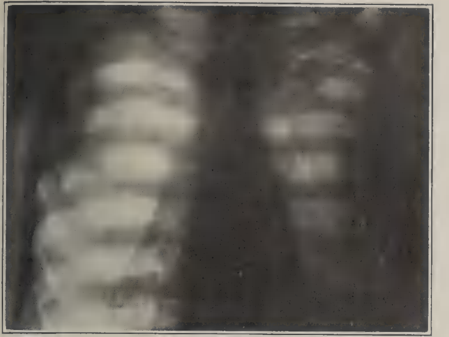
Post-mortem Examination.—General atrophy of all the organs, and especially of the liver, was noted. The small intestine was distended with gas, the walls were transparent, and there was one large ulcer in the ileum six feet from the ileo-cæcal valve, situated on the surface of the bowel opposite the mesenteric attachment. It measured one inch in diameter and had perforated in two places where recent plastic peritonitis had set in, and had become adherent to neighbouring coils of small intestine. The contents of the small bowel were similar to the stools observed in life.

The microscopical appearances of the organs were in the main similar to those described in the next case.

Case 2.—An engine-driver, aged 41, from Ceylon, where he had resided for 13 years. His illness commenced in June, 1920, with sudden explosive early morning diarrhœa and the passage of frothy, light-coloured stools. In August, 1920, he returned to England, but the diarrhœa continued, and in fact got much worse. It was accompanied by great emaciation, and in October—i.e., four months after the commencement of the illness—the tongue symptoms set in, and at the same time small yellow and very painful aphthæ made their appearance on the sides and tip of the tongue, as well as on the mucous membrane of the mouth.

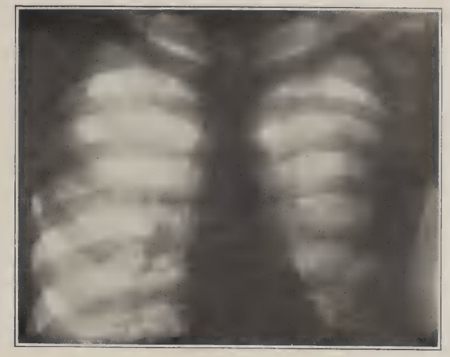
DRS. B. HUDSON AND L. HILL: HELIOTHERAPY IN PULMONARY TUBERCULOSIS.

FIG. 1.



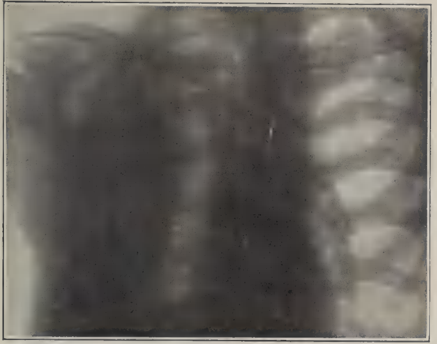
Case 1.—Radiogram taken Dec. 27th, 1922, showing thickening of pleura on left side.

FIG. 2.



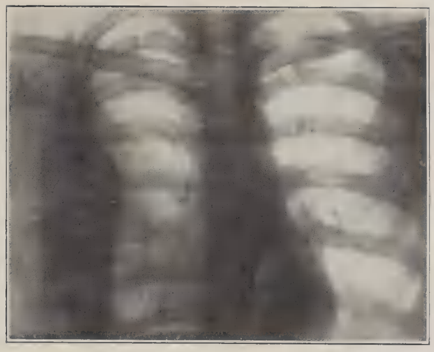
Case 1.—Taken April 16th, 1923, after a course of sunning, showing great improvement.

FIG. 3.



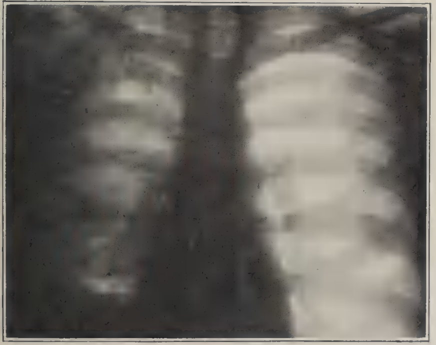
Case 2.—Taken March 24th, 1922, showing extensive pleural thickening over whole of right lung.

FIG. 4.



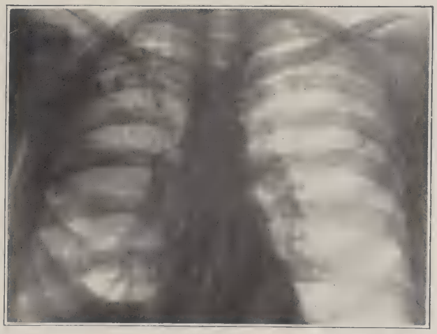
Case 2.—Taken Nov. 10th, 1922, showing improvement after a course of heliotherapy.

FIG. 5.



Case 3.—Taken March 7th, 1923.

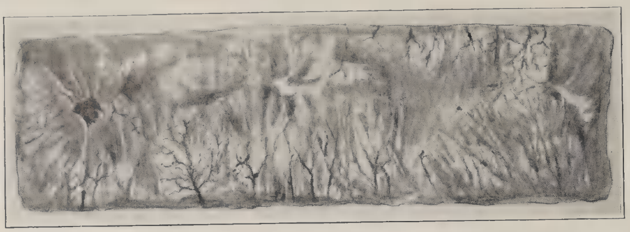
FIG. 6.



Case 3.—Taken Nov. 20th, 1923.

DR. P. MANSON-BAHR: MORBID ANATOMY AND PATHOLOGY OF SPRUE.

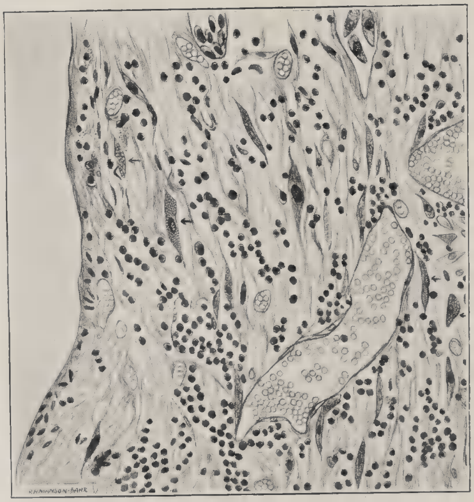
FIG. 1.



From a drawing by the Author.

Lower portion of ileum, showing ulceration with production of patches of diaphanous and attenuated bowel. The enlarged and dilated nutrient vessels can be seen in the submucosa. The bowel is viewed as a transparent object.

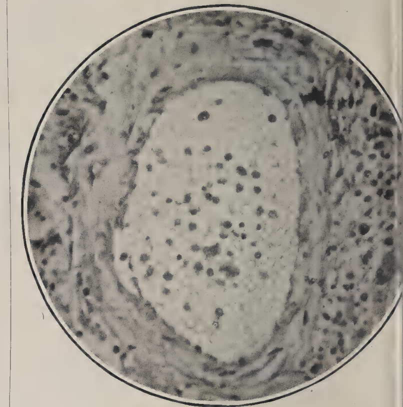
FIG. 2.



Section through base of ulcer (camera lucida), showing deposition of lipofuscin, dilatation of capillaries, and round-cell infiltration. × 175. Arrows indicate the pigment-containing cells.

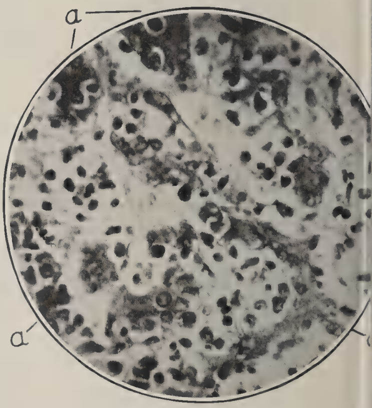
DR. A. DINGWALL FORDYCE AND DR. W. GRANT McAFEE: TENDENCY OF THE NEW-BORN TO JAUNDICE.

FIG. 1.



Hepatic artery packed with erythrocytes, showing also the increased numbers of nucleated cells—viz., erythroblasts, &c. × 400.

FIG. 2.



Liver showing surviving columns of atrophying and degenerating hepatic cells (*a a*), and the great increase of nucleated cells in and about the sinusoids. The erythrocytes have disappeared owing to post-mortem change. × 500.

He was admitted to hospital on Oct. 14th, 1920. The condition on admission was as follows: He was a big-made man, who had obviously lost weight—according to his statements already 2 stone—and now weighed 9 st. 6 lb. The tongue was pointed, glazed, and intensely hyperæmic. There was one typical sprue ulcer, almost the size of a threepenny-piece, at the tip. The mucous membrane of the mouth was engorged, especially at the inner surface of the under-lip. The abdomen was distended with gas, and the stools were large and quite typical of the condition. The patient looked extremely ill, and his skin was loose and inelastic. Secondary anæmia was present in a marked degree; hæmoglobin 70 per cent. normal; red blood corpuscles 3½ million. The stools, numbering between three and four in 24 hours, were large, frothy, and light-coloured, weighing 20 to 30 oz., and in every way typical. The urine was highly coloured and contained urobilin. The physical examination of the patient revealed little save some diminution in liver dullness and tympanitic distension, especially of the small gut. On being placed on milk treatment immediate improvement took place, increase of weight, and quiescence of symptoms. After six weeks in hospital he was discharged to convalescence, but returned on Jan. 4th, 1921, with an exacerbation of the condition. He was then desperately ill, and the diarrhœa continued in spite of several kinds of treatment, with loss of weight approximately averaging 3 lb. a week. The diarrhœa varied, but was apt to recur suddenly without any apparent cause. The stools became liquid and curdled, being very offensive and greenish in colour, and from time to time contained thick mucus and blood. Sigmoidoscopic examination of the rectum revealed merely a superficial pink hyperæmia. Towards the end the stools became more bilious, while pigmented spots appeared around the hair follicles on the abdomen, and hæmorrhages on the back of the hands and forearms. At this time the patient complained of great pain in the lower part of the abdomen. Throat symptoms were also noted, the gullet appeared raw, and the patient had great difficulty in swallowing. Considerable diminution of the liver dullness took place, reaching merely from the eighth rib to the costal margin. Death took place suddenly on April 28th, 1921. He then weighed 6 st. 7 lb.

Post-mortem Examination.—At autopsy, 12 hours after death, the skin was bright lemon-coloured, with entire absence of subcutaneous fat. Petechial hæmorrhages were present, especially on the arms and legs. On opening the abdomen peritoneal pus was found in the right iliac fossa. Small petechial hæmorrhages were noted in the posterior peritoneum, as well as on that covering the large intestine. General plastic peritonitis was noted in the pelvis as well as the last two feet of the ileum, which was hæmorrhagic and covered with solidified lymph; the descending colon and the rectum were in a similar condition.

The mucous membrane of the large gut appeared normal, and the surface was covered with thick viscid mucus. The mucous membrane of the cæcum was plum-coloured and partly hæmorrhagic. The main interest centred in the ileum. The mucous membrane was acutely inflamed, with diaphanous transparent patches. Twelve ulcers of varying sizes, situated on the surface opposite the peritoneal attachment, were found, separated from each other at regular intervals of about 9 inches. The greatest number of ulcers was found in a length of gut about 4½ feet. These ulcers were more or less of the same size, roughly oval in shape, with puckered, rolled margins, and hæmorrhagic bases. When held up to the light they were found to be translucent, and in all of them actual perforation of the bowel had occurred. In size they varied from 0·5 to 1 cm. (Fig. 1 on Plate). The ulcers had no relation apparently to Peyer's patches, which were normal in appearance. The upper part of the ileum and jejunum were slightly hyperæmic, and in the upper part of the jejunum one small ragged ulcer, 3 mm. in diameter and similar to those already described, was present. The mucous membrane for an area of 3 inches around this spot was inflamed. The mucous membrane of the duodenum showed catarrhal changes.

The fæcal contents of the intestinal canal were also of interest. The lower part of the duodenum and ileum were filled with light-coloured, fluid, sprue-like fæces, which were entirely odourless. In the large intestine the colour was similar, but they were more consistent and offensive. The mesenteric glands were enlarged, pink, and injected. As regards other organs there is little to note, save a diminution in weight, as shown by the following table: The liver weighed 34½ oz., spleen 4¼ oz., lungs 17 oz., kidneys 4½ oz. each, heart 5 oz. The liver gave a marked blue ferrocyanide reaction, indicating that an extensive hæmolysis had taken place. The gall-bladder, which was collapsed, contained a few c.cm. of amber-coloured bile.

Cultures were made from all the organs, as well as from the mucus, throughout the whole intestinal canal, both in nutrient as well as in glucose broth. No yeast cells were seen or growth obtained from any of these situations. Scrapings were made from the ulcers themselves, and examined under a dark-ground illumination for the detection of spirochætes or other characteristic appearances without success. Tuberculous infection was definitely excluded. The tissues were all examined microscopically, of which the following is the report:—

Morbid Histology.—Tongue: There is an almost total denudation of epithelium, and the subepithelial papillary structures are irregular, with hyperplasia of the connective tissue. Brownish-yellow pigment is present, either as fine granules or in aggregated masses up to 10 μ and over. These are sparse in the deeper layers of the epithelium, more numerous in the subepithelial connective tissue. The larger individual granules are situated in the upper part of this tissue, the aggregations in the deeper layers. In the muscle area they are very rare, and, when present, are in the inter-fibrillar connective tissue, not in the muscle itself. The capillaries generally are congested.

Small intestine: Jejunum and ileum. Save at the site of the ulcerations, no general loss of surface epithelium appears to have taken place, though, on account of post-mortem changes, this point is difficult to determine. As I have already pointed out in my studies on this disease in Ceylon,[4] there is a general atrophy of the villi themselves due to fibrosis, and a diffuse round-cell infiltration of the whole of the mucosa. There is also a general fibrosis of the submucosa and dilatation of the capillary vessels. In the tissues underlying the ulcers are numerous granular masses of a yellowish-brown pigment (hæmofuscin), but beneath the lateral margins pigmentation becomes more scanty. In the tissue itself lymphocytes are the predominating cells, while fibroblasts are few, eosinophils scanty, and polymorphonuclears almost entirely absent. Masses of pigment can be distinguished in the neighbourhood of the muscularis mucosæ, where it is for the most part enclosed in endothelioid cells, the nuclei of which in some cases appear to have been displaced or destroyed by the accumulated pigment granules. Appropriately stained sections failed to reveal any micro-organisms, save in the superficial necrotic layer forming the base of the ulcer.

Pancreas: Is to all appearance normal; the cells and nuclei stain well, there is no infiltration, no atrophy of cells, and no pigment seen.

Liver: Some degree of fatty metamorphosis is seen in the periphery of the lobules, and in these parts also many cells contain a very finely granular yellowish-brown pigment. In certain areas all the cells show this, but here, too, the peripheral cells are much more densely packed with it. There is no increase of connective tissue, nor any indication of inflammatory reaction.

Kidney: Very little change. In some areas the epithelial cells stain badly—probably a necrobiotic condition. The vessels generally are congested, and a few of the convoluted tubules contain hyaline material.

Spleen shows increase in connective tissue, trabeculæ prominent. Vessels congested, and here and there are minute extravasations. Many of the pulp cells are filled with finely granular dark-yellow pigment, or with round masses similar to those seen in the small intestine. In some areas every cell contains this pigment. The interstitial tissue does not show any.

Large intestine: Does not show in this case any subepithelial vascular infiltration nor any pigment-bearing cells as recorded by Fischer and v. Hecker.

There is evidently a remarkable similarity in the gross pathological changes and finer histological details to the description given by the last-named workers. The essential anatomical lesion in sprue appears to be an ulceration of the small intestine which, if it continues long enough, leads to the complete atrophy of the villi, such as is observed in the chronic stage of the disease, and one may surmise that the aphthous ulcers which commonly occur in the mouth and on the tongue in sprue are part of the same pathological process. But probably the complete denudation of the tongue, the shrinkage of the various viscera, and the extreme atrophy of the small intestine which is seen in these cases are to some extent ascribable to malnutrition.

Pathological Lesions in Relation to the Clinical Phenomena.

Are the pathological lesions in these cases sufficient to account for the well-recognised clinical phenomena of sprue? First, as regards the stools, these are characterised by their large size, their gaseous character and absence of the customary fæcal pigment, or stercobilin. The bulk of the fæces can be accounted for by the large amount of non-absorbed fat which they contain. Recent analyses seem to show that an explanation may be found in failure to absorb the fats already digested by the pancreatic juice. The total fat content of the fæces in sprue varies from 34–57 per cent.[5] (sometimes as high as 63 per cent., Willmore) of total fat in the fæces, a figure which is greatly in excess of the normal (15–25 per cent.), while the fatty acids preponderate over the neutral fats and soaps in a proportion of 3 : 1 or 5 : 1 (J. D. Thompson). The fat has therefore been digested, but cannot be absorbed through the villi of the small intestine; this may be due either to their actual destruction or to the chronic inflammation interfering with the passage of the digested fat into the lacteals. Sections of the small intestine show a widespread round-celled infiltration throughout the mucosa.[4]

Recently attention has been drawn to the close similarity between cœliac disease in children and sprue. The resemblance really lies in the stools, for in many other respects the two diseases are distinct. In cœliac disease[6] the essence is a mal-absorption of fat in the diet, probably due to a digestive fault. The fæces contain 30–80 per cent. of fat, of which the greater proportion, as in sprue, is a fatty acid. There is some evidence that in this disease the pathological lesion lies in an obstruction of the lacteals themselves, not in the mucosa, as in sprue.

It has long been known that cases of tabes mesenterica may pass copious greasy offensive stools somewhat resembling those of sprue. Ryle[7] has recently pointed out that the inability to absorb fats in this instance is to be ascribed to obstruction of the lacteals by tuberculous mesenteric glands, and it is probable that this is also the essential lesion in cœliac disease.

In complete destruction of the duct of Wirsung copious pale greasy stools are passed, and in this case the amount of unaltered fat in the fæces may rise to 50 or even 90 per cent.[7] of the total, while the neutral fats are greatly in excess of the fatty acids, but in this case stercobilin is present in the fæces, although its colour is masked by the fat. In pancreatic disease the diastatic test of the urine affords aid in diagnosis, but in cases of sprue I have investigated the diastatic value is invariably low, thus indicating that it is not the pancreas that is involved. The pale colour of the sprue stool is to be attributed to the excess of unaltered fats and fatty acids. The normal fæcal pigment stercobilin is present, but has become reduced, apparently by abnormal or excessive bacterial action, into a colourless compound, but which on oxidation rapidly becomes converted into brown pigment.[8] The appearance, size, and chemical composition of the sprue fæces, as well as the pigmentary changes, can, on the basis of our present knowledge, be ascribed to destruction of the absorption surface of the ileum, and to hurrying on the contents of the jejunum through the large gut.

Should this view be correct, and the main phenomena of sprue be attributable to a mechanical interference with digestion, then symptoms similar to those of sprue should be reproduced by other diseases involving the mucous membrane of the ileum. That this may be so is illustrated by the following case which, through the kindness of Dr. J. G. Willmore, I am permitted to quote. The case was generally regarded as one of sprue; the fæces were quite typical and contained 53 per cent. of fat. Later, as symptoms of intestinal destruction supervened, a laparotomy was performed, and a malignant growth of the ileum removed, after which the fæces resumed a more normal size and colour, and the fat content was reduced to 25 per cent. And, apparently in extensive tuberculous ulceration of the ileum, a similar fatty sprue-like stool is produced.

Secondly, as regards the anæmia. A certain degree of blood destruction is present in nearly every case of sprue; as a general rule, it is most marked in long-standing cases, and in them appears to be consequent upon the intestinal symptoms. In extreme cases the blood picture may resemble that of pernicious anæmia and is of the aplastic type. But, on the other hand, in some advanced cases anæmia is not always noticeable. It has been suggested that the presence of anæmia is dependent upon achylia. But it is not in every case of profound sprue-anæmia so far investigated that a normal or even excessive hyperchlorhydria is present; on the contrary, fractional gastric tests in the majority of ordinary cases give a normal acidity curve. (Recent analyses of my own cases.)

In my opinion the hæmolysis is consequent upon the ulceration of the small gut, and that a very considerable degree of blood destruction takes place in the gut wall at the base of the intestinal ulceration can be gathered from a study of microscopic sections (Fig. 2 on Plate), when destroyed blood pigment can be distinguished within the phagocytic cells. That a very active hæmolysis occurs in sprue can be judged by the ferrocyanide reaction in the liver, which was most intense in the two cases which form the basis of this study. I have also[11] previously remarked upon the presence of Russell's bodies in sprue tissues, especially in the spleen pulp; these bodies are regarded by Woodcock as the result of hæmatophagy and as possibly due to some specific hæmolysis, but, at any rate, they are present in tissues in which rapid blood destruction is taking place.

The Question of a Specific Organism.

Is there any evidence that a specific micro-organism is responsible for the specific lesions of sprue? The presence of yeast fungi in the intestinal contents, the buccal cavity, and fæces of sprue has attracted a considerable amount of attention. Originally these organisms were considered by Kohlbrugge as identical with *Monilia albicans*, a view I have always endorsed. At present I regard these organisms as merely a superimposed secondary infection, such as is liable to occur in any prolonged wasting disease, such as diabetes, tuberculosis, carcinoma, &c., and as by no means peculiar to sprue. Furthermore, I am of the opinion that a yeast infection in sprue is much more likely to occur within the tropics, and then only in advanced cases of this disease. It will be noted that in the two cases under review these organisms were entirely absent, both from the fæces during life and the viscera after death, although cultures on appropriate media were made under the most favourable conditions.

Ashford,[14] on the other hand, considers that sprue is a mycosis of the intestinal canal superimposed upon some food deficiency, and that the pathogenic agent is a specific species of yeast cell—*Monilia psilosis*, distinguishable from *Monilia albicans*—the thrush fungus. His theory is that in sprue there is a glandular deficiency in which the pathogenic fungus *Monilia psilosis* finds a congenial medium in which to multiply. This view has not received any great measure of support.

McCarrison[15] has shown that atrophic changes in the small intestine of monkeys may be produced by a vitamin-free diet, but, on clinical grounds, there is no evidence that the lack of vitamins plays any part in the production of sprue, at any rate, in Europeans in the East. Scott[16] has put forward, as a plausible hypothesis, that sprue may be due to an error of calcium metabolism. Many of the symptoms may be ascribed to calcium deficiency, which ultimately produces an ulceration of the small intestine and the passage of an excess of calcium salts in the fæces, and in a recent paper Ryle[7] ascribes tetany and other symptoms of cœliac disease (which are also common to sprue) to excessive excretion of the same substance. These suggestions, though somewhat indefinite at present, afford food for reflection, and indicate lines upon which future research should be based.

I am greatly indebted to Dr. H. H. Scott for critical examination of the histological specimens, while to Dr. H. B. Newham, C.M.G., Director of Pathology at the London School of Tropical Medicine, for the preparation of microscopic sections, and to Dr. A. L. Gregg, superintendent of the Hospital for Tropical

Diseases, for material assistance, my best thanks are due. Dr. J. G. Willmore has assisted me with suggestions based upon his own recent experiences of sprue.

THE TENDENCY OF THE NEW-BORN TO JAUNDICE:

WITH REPORT OF A CASE OF GRAVE FAMILIAL JAUNDICE.

BY A. DINGWALL FORDYCE, M.D., F.R.C.P. EDIN.,
PHYSICIAN, ROYAL LIVERPOOL CHILDREN'S HOSPITAL;
AND
W. GRANT McAFEE, M.B., CH.B. EDIN.

(With Illustrations on Special Plate.)

IT is a universally recognised fact that new-born babies tend to become jaundiced; the reason for this fact is still to seek. There is peculiar difficulty in distinguishing between the physiological and the pathological in the new-born; the results of antenatal and natal environment are often apparently overwhelming—for a time, at least—and variations in either entail labile boundaries to the sphere of physiology. It appears that about one out of every two babies born is jaundiced within the first few days of life, and that, so far as can be determined, the presence of this jaundice in itself does not adversely affect the prognosis—i.e., that it is not evidently pathological. As explanation of the symptom of jaundice in these cases Hess[1] favours the work of Ylppo[2] as showing that it is hepatogenous in origin, and considers that a hæmatogenous origin can be excluded; Rolleston[3] favours the theory of a hæmolytic origin and adduces the work of McNee[4] with the van den Bergh test in support; and Ritter von Reuss,[5] while adhering to no particular theory, says, "Whether icterus neonatorum rests on a uniform ætiological basis, or whether it be the outcome of various factors, it is none the less justifiable to speak of icterus neonatorum as a definite entity owing to the peculiar tendency shown by the new-born towards this condition."

The symptom of jaundice is often met with in the new-born; its cause is still undetermined and possibly varies in different cases, a jaundice which is commonly regarded as physiological. Much more rarely this symptom is also met with as one expression of a serious pathological condition. Jaundice of grave significance—icterus gravis as distinct from icterus neonatorum or physiological jaundice—occurs as a result of one of three possible pathological conditions: (1) hepatic deformity—e.g., congenital obliteration of the bile-ducts; (2) infection—e.g., obvious sepsis—sometimes congenital syphilis; (3) hæmorrhagic disease of the new-born. Included in the second category are Buhl's disease or acute fatty degeneration of the new-born, and Winckel's disease or afebrile cyanosis and jaundice with hæmoglobinuria.

In all these cases jaundice, while a striking symptom and often the outstanding symptom, is but a subsidiary phenomenon in the systemic complex; and while in cases of gross deformity, disease, or infection the differentiation from simple icterus neonatorum may be easy, yet there are many borderline cases in which the diagnosis is often one of the greatest difficulty. We meet also with cases of habitual icterus gravis or grave familial jaundice of the new-born. Such cases are those of successive infants in a family becoming jaundiced very soon—a few hours to a day—after birth, dying in coma and sometimes with convulsions, and post-mortem examination failing to reveal a cause. This category, like most others dealing with neonatal jaundice, is somewhat indefinite. Ritter von Reuss (loc. cit.) "is doubtful whether we are justified in assuming a clinical uniformity of the cases." Several or even many cases in one family may result from various and different causes.

But whatever may be the cause—and here again are rival theories as to infection and primary functional abnormality of the liver—published reports support the contention that such a clinical entity exists. Rolleston,[6] in 1920, was able to collect 130 cases, and of these 100, or 77 per cent., proved fatal. He suggests that "in its most complete form the disease is hereditary, the mother becoming jaundiced during the pregnancies of jaundiced infants, and that the usual form is an incomplete manifestation of the morbid process."

Within the past 20 years there have been many publications on the subject, and many published cases do not appear justly to fall within the category. Thorling[7] rejects Rolleston's suggestion that in the fully developed condition the mother is jaundiced, and throws doubt on many cases accepted by him.* Of cases accepted by both authors are, among others, those of Auden[8] and of Busfield[9]—both striking instances. Auden describes "a series of fatal cases of jaundice in the new-born occurring in successive pregnancies." Out of 15 pregnancies there were four survivors—the majority of the children dying, jaundiced, within a few days of birth. Some, however, lived a few months, but none except the four survivors lived longer than eight months. In both this series and that of Busfield the pregnancies followed one another in quick succession and in both cases the first child was not affected. Busfield noted that with succeeding pregnancies there was greater tendency to early death of the infant. Auden was of opinion that "the disease is an example of an acute toxæmia, due to some profound chemical disturbance, rather than to the products of a bacterial infection."

Before and since that time various other theories have been advanced, but still we have no proof. An interesting post-mortem fact noted in many cases, but not in all, is the jaundiced condition of the basal ganglia of the brain, due to necrotic changes giving rise to imbibition of bile-pigment.

A Case of Grave Familial Jaundice.

At present we have little knowledge of the intra-uterine and labour conditions in these cases, and the following case is published as an additional item of information:—

Mrs. X. is one of a family of eight brothers and sisters. Her father died of cancer at the age of 59, and her mother died of influenzal pneumonia at the age of 69. She was the seventh child in the family and was born nine years before her father's death—while he was in good health. Of her four brothers, one was stillborn (the fourth child), one died, aged 15 years, of pneumonia, one is in good health and unmarried, and one is in good health, married, but has no children. She has three sisters. The eldest was slightly jaundiced at birth. She enjoys good health, is married and has one son, aged 17, in robust health. She has had no subsequent child and no miscarriage. The second sister also enjoys good health and is married. She has two children—a boy, aged 13 years, who has always been well, and a girl, aged 8 years, who is also well, but was severely jaundiced at birth. The third sister suffers from indifferent health. She is married but has no children. Her condition is ascribed to "chronic constipation, possible appendix trouble, toxæmia." She has had various forms of treatment, including vaccines and thyroid extract.

---

* Blomfield: Brit. Med. Jour., 1901, i., 1143; Arkwright: Edin. Med. Jour., 1902, 12; Duguid: Brit. Med. Jour., 1906, i., 319; Nason: Brit. Med. Jour., 1910, i., 989; Tylecote: Med. Chron., 1914, 58.

Mrs. X. herself was born in 1891 and was normal at birth. During early childhood she enjoyed fair health and suffered from scarlet fever, "slight dysentery," and German measles. During later girlhood her health was indifferent, but she was seldom unable to carry out the day's duties. She suffered from mumps, varicella, and "lack of vitality," and received medical treatment and spinal massage for neurasthenia. She was married in 1915 when aged 24½ years.

Mr. X. is one of a family of six brothers and sisters and is the youngest of the family by seven years. At his birth his father was aged 45 and his mother 41. His father died aged 83 of old age, and his mother, aged 72, of cerebral hæmorrhage. One brother died in infancy, two are well and unmarried, and one is well and married, with three children (girls, all alive and healthy). His sister is strong, married, and has five healthy children, all girls. He was born in 1885, prematurely. He enjoyed a robust, athletic boyhood and manhood, and at his marriage in 1915 was aged 30½ years. He served with the infantry in France from January, 1916, till April, 1919, and suffered slightly from D.A.H., due to gas poisoning and strain. He was passed for insurance as a first-class life in June, 1922.

After marriage Mrs. X. appeared well, had a good appetite, and slept well, but lacked energy and felt cold severely. She was frequently worried and depressed, lacked confidence, and disliked being alone. She suffered from marked constipation, to relieve which constant medicinal treatment was necessary. The constipation steadily increased in severity after the birth of her first child in 1916 and was treated by one of us (W. G. M.) by means of paraffin, phenolphthalein, cascara, and mag. sulph. In April, 1920, she suffered from influenza. She has given birth to four children, and in all four pregnancies has been very free from morning sickness, and has had no albuminuria.

First Child.—Male, born Oct. 1st, 1916. Labour normal, conducted by one of us (W. G. M.) under scopolamine and morphine. The infant was healthy and there was slight jaundice after birth. He is alive and has always been exceptionally strong and healthy.

Second Child.—Female, born Sept. 28th, 1920. The labour was normal under scopolamine and morphine (W. G. M.). Liver large at birth, extending to below the umbilicus. No enlargement of spleen. Jaundice developed very shortly after birth, and increased in severity till fourth week. Baby nursed at breast for four weeks, and thereafter fed with glaxo. The jaundice after this somewhat decreased. The whole time, however, the baby took food very badly ; much distension of intestines. Motions small and latterly constipated. Bile present in fæces, and absent in urine. No vomiting or hæmorrhage. Baby very sleepy and dazed, and gradually became more comatose. Died when aged 2 months, and was seen by one of us (A. D. F.) the day prior to death. At this time she was deeply jaundiced and so comatose that she was unable to swallow and was fed by a stomach-tube. She had a peculiar, cretinoid appearance, no hæmorrhages, and such marked abdominal distension that palpation revealed nothing but great intestinal distension—almost certainly of the small intestine. A blood film threw no light upon the case. To clear up the diagnosis of the case a Wassermann test was suggested, but could not be obtained. Intimate family history was, however, known and strongly negatived a specific cause. At this time the possibility of the diagnosis of congenital family jaundice was discussed but discarded, because, although the jaundice had recently improved, the baby's general health had become progressively worse. The improvement in the jaundiced condition was possibly due to weaning. Unfortunately no post-mortem examination could be obtained.

Third Child.—Female, born Feb. 15th, 1922. Labour normal under scopolamine and morphine (W. G. M.). Baby deeply jaundiced ; great enlargement of liver and spleen. No hæmorrhages. Baby well nourished. A blood film showed large numbers of basophile cells. She died when 1 day old.

Post-mortem Examination.—This examination was carried out by Dr. L. S. Ashcroft the following day. He reported as follows: "There were no obvious naked-eye lesions present anywhere, except a very enlarged liver and also a large spleen, which otherwise showed no macroscopical lesions. I could not find any congenital abnormalities present in any organ. I took some of the liver, spleen, pancreas, and thymus for section work, and also some of the heart's blood. The heart's blood was negative for a Wassermann reaction, and in none of the sections could I detect any spirochætes, nor was there anything histologically suggesting syphilis. Further there was no suggestion of an inflammatory condition."

Microscopical Examination.—Prof. E. Glynn examined and reported as follows on the section of liver: "Report on one section of liver, stained with hæmatoxylin and eosin and showing a considerable amount of post-mortem change. The appearances are remarkable owing to: (*a*) the presence of only about one-third the normal number of hepatic cells—the survivors are arranged in small isolated masses and slender columns (see Special Plate); (*b*) the presence of large numbers of nucleated cells lying between the surviving hepatic cells. All parts of the lobule are about equally affected by these changes. The epithelial cells are distorted and often very narrow from degeneration or from atrophy—partly pressure atrophy. The cytoplasm of many shows evidence of fat of the 'degenerative infiltration' type, for the vacuoles are very fine, and the nuclei, when present, are central. The erythrocytes in the two hepatic arteries present in the section are perfectly preserved, but those in the hepatic and portal veins have almost completely hæmolysed—evidently from intestinal toxins developing post mortem. The sinusoids show a great increase in the number of nucleated cells, but owing to the difficulty of recognising the endothelial or Kupfer cells which partly line the sinusoids, it is impossible to state what proportion of these nucleated cells are inside or outside the sinusoids. The majority of the nucleated cells are probably lymphoidocytes—i.e., the primitive blood-cell from which myeloblasts, lymphoblasts, and erythroblasts develop. A large number of erythroblasts are certainly present, for many of the cells have a round deep blue staining nucleus to which are attached fragments of homogeneous red cytoplasm. The blood in both the hepatic arteries shows an increase in the number of nucleated cells ; many are certainly erythroblasts. The bile-ducts are normal ; the bile canaliculi cannot be seen ; apparently bile-pigment is absent. There is a slight cellular infiltration of Glisson's capsule, but no fibrosis in them or in other parts of the liver.

"*Comments.*—Formerly most of the nucleated cells in the sinusoids and hepatic artery would probably have been regarded as lymphocytes and the pathological condition classified as fœtal leukæmia (see Reuss, loc. cit., p. 330). It is, however, almost certainly one of 'erythroblastosis.' In other words, the vascular areas, or 'herde,' of blood formation producing erythroblasts, myeloblasts, &c., which are normally present in fœtal life have not only *persisted*—as they usually do till shortly after birth—but have also *enlarged* and become diffused throughout the liver lobule. Erythroblastosis is always associated with enlargement of the spleen and liver, which was observed in this case.

"The histological appearances of this section resemble those seen in the liver of a 37 weeks' old macerated and jaundiced fœtus, described by Dr. N. B. Capon in an interesting paper on 'General Œdema of the Fœtus' (Jour. Obstet. and Gynæcol. Brit. Emp., 1922, vol. xxix., No. 2, Case 8). Here, as in the case under discussion, there was no œdema. In erythroblastosis, as Capon points out, the fœtus responds to an 'impairment of nutrition' by an increase in blood formation. The section described here throws no light on the cause of the impaired nutrition, nor on the cause of the jaundice."

Fourth Child.—In the beginning of October, 1922, Mrs. X. again found herself pregnant. She was in good health, but both she and her husband were much perturbed since a clear diagnosis of grave familial jaundice had been explained to them with a very guarded prognosis as to the probable condition of future children. She at once agreed to submit to detailed examination with a view to treatment during pregnancy. Thorough clinical examination by one of us (W. G. M.) showed her to be in sound health, active, and energetic, but to suffer still from marked constipation. Dr. Ashcroft, on Oct. 13th, examined the blood Wassermann reaction, which he found completely negative. He also examined a catheter specimen of urine. This showed, in the centrifuged deposit, "a few bladder cells, no renal cells, no renal casts ; no red blood cells ; no pus cells. Culturally: *Staphylococcus albus* only (most probably saprophytic or possible contamination)." Dr. R. Coope's report (Oct. 16th, 1922) was as follows:—

"Blood: Coagulation-time normal ; fragility of red blood corpuscles normal ; Van den Bergh's test for bilirubin completely negative. By Folin and Wu's method—sugar (three hours after a mixed meal), 105 mg. per 100 c.cm. ; non-protein nitrogen (on simple mixed diet), 26 mg. per 100 c.cm. Red blood corpuscles, 4,300,000 ; white blood corpuscles 6800 (polymorphs 70 per cent., large lymphocytes 8 per cent., small lymphocytes 21 per cent., eosinophiles 1 per cent.) ; hæmoglobin 79 per cent.

"Stools: Nothing abnormal found (either in stools of a milk régime or those of a controlled test diet).

"Urine: Sugar, blood, bile pigments and bile salts, and acetone bodies absent. Urobilin, no excess. Albumin, slight amount. Indoxyl, markedly excessive. Titratable acid, 18 c.cm. decinormal soda. Total nitrogen, 0·66 g. per cent. Ammonia, 27·2 mg. per cent. Urea, 1·41 g. per cent. Ammonia ratio 4·1 per cent. Diastase, 6 units. Deposit: The catheter specimen showed no pus cells or bacilli but a few hyaline and hyalo-granular casts. The first (24-hourly) specimen which I examined showed quite a fair number of casts—hyaline, hyalo-granular, and definitely granular casts. A third specimen (morning specimen) also showed casts, though not quite so numerous as in the 24-hourly specimen. Urea-concentration test (hypobromite method): First hour after 15 gm. urea ingested, 4·5 per cent.; second hour, 5·0 per cent.; third hour, 5·2 per cent.

"The positive findings are these: slight but appreciable albuminuria, granular casts. The blood non-protein nitrogen is not higher than normal, even for pregnancy (Folin and Wu's whole-blood method used). Urea concentration is very good. It looks, therefore, as though there has been, or is, a small renal lesion, but no obvious impairment of renal function, even when the strain of 15 g. of urea is imposed upon the kidney."

She was also examined by a gynæcologist (Dr. Leith Murray), who reported on Oct. 10th: "I find her both by history and by examination 12 weeks pregnant. Bi-manual examination discloses no abnormal feature."

With such data to hand she consulted Dr. Robert Hutchison as to her régime during pregnancy. With a view to preventing intestinal toxæmia he recommended a lacto-vegetarian diet, advised the use of senna pods as a laxative, and also calomel, gr. 1/20, twice or three times daily. Acting on this advice, she passed through an uneventful pregnancy and on April 20th, 1923, a baby boy was born at full term. Scopolamine and morphine were used during labour and the baby weighed 8 lb. at birth and appeared perfectly healthy. He has shown no sign of jaundice, was reared on the bottle (cow's milk mixture), throve extremely well, and is now aged 6 months, weighs 14 lb. 11 oz., and is 26 in. in length.

We are greatly indebted to Drs. Ashcroft and Coope, Prof. Glynn, and Drs. Hutchison and Murray for permission to publish their reports.

SURGICAL TUBERCULOSIS IN EGYPT.

AN ANALYSIS OF 2500 CASES.

BY ROBERT V. DOLBEY, M.S.LOND., F.R.C.S.ENG.,
DIRECTOR OF THE SURGICAL UNIT; SURGEON TO THE KASR-EL-AINY HOSPITAL, CAIRO;

AND

A. W. MOORO, F.R.C.S. ENG.,
SURGICAL REGISTRAR AND TUTOR TO THE HOSPITAL.

THE incidence of bone and joint and gland tuberculosis in Egypt differs essentially from that in England to-day. Among the fellaheen or country people, and also among the urban population of Egypt, the flat bones, the bones of the skull and face, the sternum, scapulæ and ribs, the spine and ilium, and the small bones of the hands and feet are chiefly affected. The long bones and the big joints are not so commonly involved.

We have concluded an analysis of 2500 cases of surgical tuberculosis that have attended the out-patient department or been admitted to the surgical wards of Kasr-el-Ainy Hospital within the last three years. Of these, 1197 have been cases of tuberculous glands, 804 cases of tuberculosis of the flat bones, 159 cases of tuberculous peritonitis, and only 340 of the long bones and the big joints.

Source of Tuberculosis in Egypt.

It is not easy to find the source of tuberculosis in Egypt. The experience of the Government abattoirs, where a rigorous inspection of animals and meat is held, shows that cows and bulls are becoming more commonly affected. The published statistics of the Cairo abattoir have increased from 625 cases of tuberculosis in 1914 to 1807 in 1917. The best grades of beef are far too expensive for the poor of Cairo. The cows of the country are very susceptible to tuberculosis. No less than 43 per cent. of the Domain cattle, the best and best cared for cattle in Egypt, responded to the tuberculin test. The slaughter-houses of Cairo and Alexandria find that 5·2 per cent. of all animals are infected. Swine flesh, in a Moslem country, can, of course, be disregarded as a source of infection. The gamoose or buffalo, the poor man's cow in Egypt, is relatively immune to tubercle, as it is to cattle plague. Cow's milk is more expensive than buffalo's milk, and is almost entirely kept for European consumption; this, in spite of the fact that buffalo's milk is richer in fats and in casein. The milk of the poor is practically free from disease, as is his meat. The expensive bull or cow-beef is also kept for European consumption. The sheep and goat that are the common sources of the poor man's meat-supply —though the fellaheen eat meat once only in the week as a rule—are not susceptible to, or indeed infected by, tubercle in Egypt. It is in all probability the bad quality and health of the animal that is eaten rather than the susceptibility of that animal to tubercle that are the important factors. The buffalo, cow, and camel are practically never eaten by the poor unless they are sick and obviously unlikely to recover their usefulness for purposes of work or profit, and the camel is now very susceptible to tuberculosis.

There is, however, a source of surgical tuberculosis that has not yet been sufficiently explored in Egypt. Avian tuberculosis affects both pigeons and chickens. In fact, fowls are particularly prone to disease of all kinds in Egypt, to fowl plague and fowl cholera, though the incidence of actual fowl tuberculosis has not yet been fully worked out. The fellaheen, eating as they do from the mud floors of their huts, are most likely to contaminate their food with droppings of fowls which inhabit the same huts. It is the urban populations in Egypt rather than the fellaheen among whom surgical tuberculosis is the greater scourge. In this respect the incidence of disease is similar to that of Europe. It is probably to the poor quality and possibly infected nature of the meat-supply, and the great inrush of non-immune fellaheen from the villages into the now rapidly swollen towns, that we can attribute the great and rapid increase in the incidence of tuberculosis of bones and joints and glands in Egypt.

Incidence of the Disease.

Tuberculosis in general, and surgical tuberculosis in particular, is the greatest scourge in the whole country. It is the great killing disease where bilharziasis and ankylostomiasis are the great disabling diseases in Egypt. The Soudanese, with woolly hair and coal-black skins, are particularly predisposed to this disease in comparison with the Egyptian, who is a brown man with flat black hair.[1] Thirty years ago, before the improved means of sea communication brought the invalids of the world to Egypt, tuberculosis, both pulmonary and surgical, was a comparatively rare disease in Egypt. This is the experience of all the old practitioners of that time.

Immunity to Tuberculosis, Past and Present.

Tuberculosis appears to have the characters of a new disease in modern Egypt, and the population seems to have little acquired immunity to the disease. And yet if it is new to-day it was not always new. The bones of Predynastic, Dynastic, and Ptolemaic Egypt present the most marked evidences of this disease, as indeed they do of rickets, achondroplasia, and osteomyelitis. But of syphilitic diseases of bone there is not one authentic specimen. The history of Egypt presents an alternating series of great civilisations and greater catastrophes. There are the enormous urban populations like those of Memphis and of Thebes, and the periods when these civilisations were destroyed and dispersed by the invading armies that have swept Egypt from time to time in her past history. Then the population, perforce, turned to agriculture. In these alternating periods of agricultural and crowded urban populations the incidence of tuberculous disease in the bones exhumed from the graves of the various Dynastics seems to vary.[2] During the agricultural eras we find evidences of disease of the long bones and big joints such as the knee or hip; in the eras of industrial activity and the crowded life of the enormous cities of ancient Egypt we find tuberculous caries of the flat bones, the spine, the ribs, and the ilium. So marked a scourge was surgical tuberculosis in ancient Egypt that the crowded life of cities, in the rabbit warrens of mud houses as we know them to have been in those days, could hardly have been possible unless an acquired immunity to the disease had been developed. In the agricultural eras this immunity broke down. This evidence from the past, and the incidence of surgical tuberculosis to-day when the population is increasing and large industrial populations are developing, suggests that tuberculosis of the long bones and the big joints is the result of infection by a strain of tubercle bacilli of attenuated virulence in a race that has gained its immunity; whereas the type of disease attacking the flat bones is of a new and exalted virulence in subjects with no acquired immunity.

---

[1] Madden: The Surgery of Egypt.

The *mortality* of this disease in Cairo and all the cities of Egypt to-day is very great. Among the poor urban population the death-rate is 80 per cent. in the case of gross tuberculous disease of bone with abscess and mixed infection. Even in hospital, where good food and fresh air and adequate surgical treatment are available, our experience is little different.

The *course* of the disease is very rapid; quick abscess formation and marked deformity are the rule. Mixed infection inevitably takes place, owing to the common practice of incision and drainage of the abscess instead of aspiration. As a rule the disease takes about 18 months to kill, and the end is usually from a green infective diarrhœa. Meningitis is comparatively rare as a terminal manifestation of the disease.

There are no complete official *statistics* of the disease. Hospital admissions show a greater preponderance of tuberculous disease of hip or knee or spine than in out-patients; but this is because they are of necessity bedridden cases. But if one compares the numbers of new cases of Pott's disease of the spine alone that come to out-patients every afternoon with the number of adult hunchbacks to be seen in the streets it is sufficient to carry conviction. An adult with Pott's deformity is rare in Cairo; but new cases of children with recent disease of the spine attend every afternoon.

In regard to the sharp line that can be drawn elsewhere between pulmonary and surgical tuberculosis, we have the same experience in Egypt of gross disease of the spine with unaffected lungs, and advanced pulmonary tuberculosis of the apices of the lung without involvement of the lymphatic glands of the neck.

Treatment.

The treatment of surgical tuberculosis in Egypt is very unsatisfactory. There are two surgeries in Egypt, the surgery of the poor and the surgery of the rich. For the latter there are institutional treatment, hygienic and dietetic aids, and the same conservative operations and orthopædic apparatus, designed from the point of view of restoration of function, as in Europe. But for the poor there are in general no sanatoria, no orthopædic apparatus, and only a few possible conservative operations upon joints. Spinal caries and big-joint affections with abscess formation, in which plaster and repeated aspiration fail and, especially, in which mixed infections subsequently develop, are usually hopeless. The best that we can hope for in a tuberculous knee or hip is a fixed joint. Amputation is far the safest and best functional operation in mixed infections in the limbs. Any temporising operation, such as the scraping of sinuses in tuberculous dactylitis, for instance, is commonly followed by recrudescence of the disease in other joints and other epiphyses. As a rule, plaster with a view to fixation in useful functional position in cases of pure disease of joints, or amputation in cases of mixed infection, is far the best. In the numerous class of cases where flexion-deformity exists, with active disease, treatment in plaster until ankylosis is firmly established and disease quiescent, is the only safe treatment to adopt. The deformity can subsequently be corrected by such straightening operations as subtrochanteric osteotomy.

For tuberculous caries of the spine in Egypt Albee's operation of bone grafting is an excellent procedure. From the point of view of function and stability nothing gives us so strong and rigid a spine as a bone graft. Our only alternatives are plaster jackets, which are seldom effective, and always intolerable, owing to the incredible number of vermin that collect beneath them, or orthopædic apparatus, for which there are no funds or Samaritan societies, and which have a definite market value to poor, and perhaps unscrupulous, parents. In this connexion, however, it is necessary to add that there are no more devoted parents in the world than in Egypt and in all Moslem countries, though their ignorance is often pitiable. In Albee's operation, however, the shock of the whole operation at one sitting is great, and our children are often so wasted by want of good food and by parasitic disease that we have adopted a method of performing this operation in two stages. The first consists of removal of the tibial graft and implantation in the cellular tissue of the abdominal wall; the second, after an interval of a week or ten days, of the implantation of the graft along the spinous processes.

Tuberculous glands of neck often show very promising results after treatment by X rays. Such is the common and extensive involvement of the glands in both triangles of the neck that operations, to be complete, are so mutilating and so frequently followed by recurrence as to prompt surgeons to abandon operation altogether.

Conclusions.

The conclusions at which we have arrived after the study of hospital cases, veterinary and abattoir statistics, are:—

(1) Tuberculosis, both surgical and pulmonary, is very greatly on the increase in Egypt.

(2) The type and incidence of surgical tuberculosis in the flat bones rather than in the classical long bones and joints suggest that we have here a recrudescence of the disease in a community that has lost its acquired immunity.

(3) The study of Predynastic, Dynastic, and Ptolemaic bones, extending to a period as far back as 3000 years B.C., proves that surgical tuberculosis was a disease of frequent incidence in those times. It also suggests that the type of disease affecting the flat bones developed when periods of urban civilisations succeeded periods of almost purely agricultural life in Egypt. Maceration and softening of mummified tissues, which have been successful in demonstrating certain infective organisms in Predynastic bodies, have not yet enabled us to demonstrate the tubercle bacillus. Work on this subject is still proceeding.

(4) The meat- and milk-supply of the poor in Egypt is obtained almost entirely from non-tuberculous sources such as the buffalo and goat, which are relatively immune to tubercle.

(5) Avian tuberculosis is probably a contributing cause of the incidence and development of this disease among the poor in Egypt.

(6) The development of the two-stage method of performing Albee's operation of bone grafting of the spine allows this procedure to be adopted even in young children.

THE
VACCINE TREATMENT OF OZÆNA.

BY KOZO SAKAGAMI, M.D.,
TOKYO, JAPAN.

IN 1908 Perez discovered the coccobacillus of ozæna, and in his report considered it to be the pathogenic bacterium of that disease. In the same year Skillen and Holmes also discovered a similar bacillus, and prepared from it a polyvalent vaccine which they tried clinically. In 1913 Hofer and Kofler prepared a new vaccine from the Perez bacilli, and tried it on many ozæna patients; their results were reported to the German Society for Laryngeal Diseases. As stated recently, on the strength of my studies extending over several years, I became convinced that the causative agent of ozæna is the coccobacillus of Perez and Hofer, and that therefore a vaccine treatment by this bacterium is the most reasonable of all the ozæna treatments. Through the kind assistance of several specialists I have been enabled to employ the vaccine treatment in more than 70 instances since 1919. Unfortunately some of the patients failed to continue the injections for the requisite period, in other cases the records are incomplete, so that only 30 cases remain. Even so, the following report may be of interest, as it gives some idea of the treatment.

Preparation of Coccobacillus Vaccine and its Application.

Patients clinically diagnosed as sufferers from ozæna were examined bacteriologically, and a so-called autogenous vaccine was separately prepared for each patient, these vaccines being mono- or poly-valent according to the case, monovalent for simple, polyvalent for multiple infections.

The number of bacteria present in the vaccine is ascertained by counting, and sterilisation effected by heating after Wright's method. The number of bacteria contained in 1·0 c.cm. of vaccine is also ascertained.

In my first preparation I used a comparatively small number of bacteria; in subsequent experiments, however, I found that a larger dosage is well borne by the patients and is more effective. Accordingly the number of bacteria contained in the vaccine has been greatly increased.

	Number in millions of bacteria.	
	In first preparations.	In recent preparations.
Coccobacilli ..	.. 100	500
Gram-positive B...	.. 100	400
Staphylococci ..	.. 500	1000
Friedlaender's B...	.. 100	500
M. catarrhalis ..	.. 50	200

Dosage.—Of my recent preparations (with the increased number of bacteria) I have fixed the dosage for the first injection at 0·1 to 0·2 c.cm., containing: coccobacilli, 50 to 100 millions; Gram-positive B., 40 to 80 millions; staphylococci, 100 to 200 millions; Friedlaender's B., 50 to 100 millions; *M. catarrhalis*, 20 to 40 millions. The maximum dose is 1·0 c.cm., containing: coccobacilli, 500 millions; Gram-positive B., 400 millions; staphylococci, 1000 millions; Friedlaender's B., 500 millions; *M. catarrhalis*, 200 millions.

After the first injection the dose is to be increased by 0·1 to 0·3 c.cm. up to the maximum dose, which may be maintained, or the doses may be gradually decreased again to 0·6 to 0·8 c.cm., and then maintained at this latter figure.

As to the *place of injection*, the subcutaneous tissue of the outer part of the upper arm is preferable.

Reaction.—When the doses are gradually increased, as indicated above, there is almost no reaction, and even if the injected part should become red or swollen, this will subside soon.

The *interval between injections* should be three to four days during the period for small injections (up to 0·5 c.cm.), and five to seven days for 0·6 c.cm. or above.

Autogenous Vaccines Prepared.

The total number amounts to more than 75, but here I enumerate only those used in the cases considered in this report.

TABLE I.

Current number.	Species of vaccine.	Number of preparations.
1	Coccobacilli Gram-positive B. } Mixed.	13
2	Coccobacillus vaccine.	6
3	Coccobacilli Staphylococci } Mixed.	4
4	Gram-positive B. Staphylococci } Mixed.	3
5	Coccobacilli Gram-positive B. Staphylococci } Mixed.	1
6	Gram-positive B. *M. catarrhalis* Staphylococci } Mixed.	1
7	Gram-positive B. Friedlaender's B. } Mixed.	1
8	Gram-positive B.	1
	Total	30

Clinical Trial of Coccobacillus Vaccine.

As already stated, out of the total number of ozæna patients treated with the vaccine, there are only 30 whose records are complete. It would be of little interest to go into the details of each case, so I tabulate them briefly (Table II.). When going through the table it will be seen that among the 30 patients treated there were six who presented the ozæna symptoms, but whose autogenous vaccine contained no coccobacilli; these six cases should, of course, not be taken into account when determining the value of coccobacillus vaccine. Then there are 24 cases left which received either pure or combined coccobacillus vaccine—viz., 5 cases slightly improved (21 per cent.), 11 cases fairly improved (46 per cent.), 6 cases thoroughly recovered (25 per cent.), and 2 cases with no improvement (8 per cent.). The longer the injections are continued the better are the prospects of recovery.

Condition of Blood Corpuscles of Ozæna Patients and Immunised Rabbits.

I have always endeavoured to determine the changes, if any, in the condition of the blood corpuscles of the ozæna patient after he has undergone a prolonged course of treatment with coccobacillus vaccine, as compared with the state before treatment, because in this way certain facts might be secured for judging the effects of the treatment, or some otherwise helpful ideas might suggest themselves. I have also compared the condition of the red blood corpuscles of the rabbit immunised against the coccobacillus with that of the rabbit immunised against Gram-positive bacilli, and these two again with that of the normal rabbit. The result is summarised as follows:—

(1) The number of both the red and the white blood corpuscles of the ozæna patients is remarkably low, and though both show some increase in number after the injections, the difference is only slight. Also the relative percentage of the various kinds of white corpuscles remained the same, while the hæmoglobin generally decreased.

(2) In the rabbit immunised against the coccobacillus, and in the rabbit immunised against both the Gram-positive and Friedlaender's bacilli, there appeared an equal decrease in the number of both red and white corpuscles, but no change in the specific percentage of the white corpuscles, while the quantity of hæmoglobin decreased a little.

From the above we may deduce that, if the number of blood corpuscles of an ozæna patient has not increased after the injections, the number of injections has been insufficient; and when we see that in the case of rabbits highly immunised, and, as proved by animal tests, effectively immunised, there remains still a more or less considerable decrease in both elements, especially in the white corpuscles, we may infer that infection of man with Perez's bacillus is the cause of the decrease of the blood corpuscles.

TABLE II.

Number.	Patients.	Sex.	Age.	Time of inj.	Period in months.	Species of vaccine.	Symptoms before injection.			Symptoms after injection.

N.B.—(1) In the column for "Species of vaccine," B.G + signifies the Gram-positive bacilli, S.C the staphylococci, F.D the Friedlaender bacilli, M.C the *M. catarrhalis*, and C.C the coccobacilli.

(2) In the column for "Symptoms before (after) injection," (i) signifies the stinking secretion, (ii) the crusts, (iii) the nasopharyngeal exsiccation, ††† the highest degree, †† the medium degree, † the lowest degree, and 0 the absence resp. disappearance of the symptom.

Conclusion.

If we place together the experimental results obtained so far, we arrive at the following conclusions:—

1. As various diseases of the nasal passage present a close resemblance to ozæna, the effectiveness of the vaccine treatment of ozæna patients can only be determined by applying the autogenous vaccine produced from the bacteria carried by the patient himself, and after the species of such bacteria has been ascertained.

2. My bacteriological observations show that most ozæna patients suffer from a mixed infection by the coccobacillus and Gram-positive mucus-producing bacilli; therefore the application of mixed vaccine derived from these two kinds of bacteria appears reasonable.

3. Injections of coccobacillus vaccine and mixed vaccines are the most reasonable treatment of ozæna cases.

4. Ozæna patients generally show a decreased number of red and white corpuscles, and this condition does not change after vaccine treatment. In animal experiments likewise the red and white corpuscles of the rabbit immunised against coccobacillus show a considerable decrease.

In closing this report, I express my thanks to Dr. Minokichi Kurosu for his coöperation during my clinical trials, and to Dr. Kazuyoshi Asaba and Dr. Sadayemon Sasaki for the great help given in the experiments.

NOTE ON THE TREATMENT OF EPIDEMIC ENCEPHALITIS.

BY EDWIN MATTHEW, M.D., F.R.C.P. EDIN.,
PHYSICIAN, ROYAL INFIRMARY, EDINBURGH.

DURING the present spring and in that of 1923 I have had the opportunity of seeing and treating in private and in the wards of the Edinburgh Royal Infirmary under my charge over 20 cases of epidemic encephalitis. In many the usual features were present—cranial nerve palsies, nocturnal insomnia, and drowsiness during the day. Some, in addition, had the painful myoclonic contractions, and two marked choreo-athetotic movements. The treatment of the condition is admittedly unsatisfactory. Urotropin in large doses, Pregl's iodine solution, sod. cacodylate injections, with hyoscine hydrobromide as a palliative, have all been tried, sometimes with partial success.

For many years now I have employed intramuscular injections of magnesium sulphate in chorea with considerable success, and during the past two winters I have been observing its effects in epidemic encephalitis, and I think with better results than other suggested remedies. This is particularly so in the myoclonic and choreo-athetotic types. The myoclonic and choreo-athetotic types are often very severe, are very trying to the patient, and the muscular contractions are very painful, but with magnesium sulphate injections I have never failed to stop the contractions after a few doses. The last two cases admitted to my wards were typical.

One had myoclonic contractions, very severe over the whole abdominal wall, and less so in the lower limbs. After three injections the contractions entirely ceased and did not recur. The second case had severe choreo-athetotic movements affecting the whole body, which had been present for three days before admission. During the following three days the movements became, if possible, more trying. Magnesium sulphate was then given. A difference was observed after the first injection, and after three injections the movements had almost entirely ceased. In the ordinary cases with the cranial palsies, drowsiness, &c., benefit can also be observed. After four or five injections the temperature falls to normal and the patient is less drowsy, though the ocular palsies still remain.

This treatment with magnesium sulphate is, I think, worth a further trial. A 25 per cent. solution of magnesium sulphate is used and 4 c.cm. given at each injection. The second dose is given 12 hours after the first, and the third and subsequent doses, if required, at 24 hours' interval.

Medical Societies.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

A meeting of this Society was held at the rooms of the Medical Society of London on May 30th, Colonel L. W. Harrison, the President, being in the chair.

A discussion took place on the subject of

Epididymitis.

Mr. **Kenneth Walker** said that though the gonococcal was the form of epididymitis chiefly concerned, it would be necessary for him to refer to such other forms as those due to the tubercle bacillus, *B. coli*, and other pyogenic organisms. It was the general belief that infection of the epididymis from the urethra was effected through the lumen of the vas, the exciting cause being a wave of reversed peristalsis which drove infective material downwards towards the epididymis. He did not deny this, but was convinced that another route was open to the infecting organisms. In some experiments he made 14 years ago with *B. prodigiosus* he was able to prove that organisms could reach the epididymis from the urethra even after the vas had been tied and divided. The epididymis was infected 10 to 24 hours after inoculating the urethra, and the infection was not blood-borne, as blood cultures were always negative. Later work suggested that the organisms travelled along the lymphatics in the sheath of the vas. It was known that infection descended the cord, and that the chief producer of epididymitis was irritation of the posterior urethra, trauma of the latter, in his view, opening up the lymphatics to infection. A factor of equal importance in the production of epididymitis was direct trauma of the testis; there was often a history of the latter in the cases. He was sure that gonococci were often present in tissues without producing symptoms; and if they were in the epididymis even the trauma associated with exercise would suffice to precipitate epididymitis. During the war, epididymitis was most frequent where irrigation was carried out at too great a pressure and where it was the habit to place subjects of posterior urethritis on to fatigue duty.

Preventive treatment was very important, and all irritation of the posterior urethra must be avoided during the acute stages of the disease. The tendency of the present day was towards over-treatment and over-instrumentation. Rest was very important; the cases would be halved if all acute gonorrhœa cases were kept in bed. Failing this, patients should wear suspensory bandages and take a minimal amount of exercise. He had not found atropine or belladonna definitely helpful, though they should reduce peristalsis in the vas. To prevent epididymitis occurring after prostatectomy, many surgeons ligatured the vas at the neck of the scrotum. Some French urologists had advocated that for many years, and Mr. Clifford Morson in this country favoured the practice.

Diagnosis.—With regard to diagnosis, he said the common conditions from which a gonococcal epididymitis had to be distinguished were attacks which occurred secondary to urinary infections by other organisms, such as *B. coli*, acute attacks of epididymo-orchitis associated with blood infections, such as mumps and typhoid, and from tuberculous epididymitis. Epididymitis could complicate a staphylococcal prostatitis as easily as it could a gonococcal one. The differentiation of the gonococcal from the tuberculous condition was not always easy, especially as the method of spread was the same in both. In the majority of both tuberculous and gonococcal cases, a lesion of the prostate or vesicles could be detected by rectal examination. In 22 out of 24 cases of genital tuberculosis sent to him for examination he found signs of prostatitis or vesiculitis. In early days it might be necessary to wait for a certain diagnosis.

Treatment.—When the condition had developed, two objects were aimed at in treatment: (1) the relief of pain, (2) the hastening of resolution. A third, and important, one he regarded as the prevention of subsequent sterility. All inter-urethral treatment should cease and the patient be kept in bed, which he was usually glad of, owing to the acuteness of the pain. In some, the pain was felt along the cord rather than in the testicle itself, sometimes leading to the diagnosis of acute appendix, especially if vomiting also occurred. Hot fomentations, supported by hot baths and rubefacients might give sufficient relief, especially if backed up by morphia suppositories. The form of heat application he favoured was that by diathermy, the whole testicle enwrapped in a zinc sheet which had been well padded with lint soaked in saline. This treatment was applied daily. The pressure pain could be much reduced by puncturing the swollen epididymis with a hypodermic needle, drawing off a little blood-stained serum. Americans favoured doing more: opening the tunica vaginalis and incising the swollen epididymis. Owing to the danger of dividing the epididymal canal, resulting in stricture and sterility, he did not approve of this more heroic measure.

Epididymitis and Sterility.—Mr. Walker said it was probable that gonorrhœa was responsible for at least 40 per cent. of all barren marriages, and if sterility in the male alone were taken, the figure would be even higher. Of 30 husbands sent to him by gynæcologists, he found seven cases of azoöspermia, three of which were the result of previous gonococcal epididymitis, two of mumps. When epididymitis was bilateral, the chances of sterility were very great. Cunningham and Cook (in America) found that out of 22 patients upon whom they had performed double epididymectomy, 12 subsequently showed spermatozoa in their semen; in five they were absent. No examination of the semen was made in the case of the remaining five. Finger, following the expectant treatment, found that 207 out of 242 cases of gonococcal epididymitis suffered subsequently from azoöspermia. Thus incision of the inflamed epididymis seemed to lessen the risk of sterility.

Discussion.

Major A. T. **Frost** confirmed what Mr. Kenneth Walker said as to the method of direct infection. He had been looking into the records of over 300 cases and had been struck by the fact that the urethra never showed a posterior infection. In the army a crop of epididymitis cases in the winter usually meant that there was a football team, and strenuous games were played. The sudden exertion caused either injury or a reflex disturbance which spread the disease up the vas. In the army it was rare for a case of epididymis to last beyond ten days, though slight enlargement of the organ might be left longer. Little was done for it except resting the patient in bed and injecting sulpharsenol, though he did not regard the latter as a specific. It had no effect when the patient was at his worst, but was useful on the upward rise and when the infection was clearing up. It was an excellent analgesic. Secondary infection, mostly streptococcic, probably found its way in by irrigation. He relied on vaccine-therapy as much as ever, and a combination of this with sulpharsenol he regarded as the best non-drastic method of attacking the disease.

Mr. **Claude Mills** said cases did best which were put on to vaccines as a routine measure. Patients should wear a suspensory bandage from the date the gonorrhœa started; it lessened the risk of subsequent epididymitis. Often the fluid in the tunica vaginalis contained gonococci, though the patient might have no symptoms of epididymitis, showing, he thought, that the gonococci probably got through the lymphatics.

Captain **Carminow Doble** said he had found atropine very helpful in epididymitis, and the same was true in his experience of sulpharsenol.

Major **Dawson** was able amply to confirm the statement as to the harmful effects of football in these cases of gonorrhœa in producing epididymitis, for in certain hospitals in France during the war there was a high epididymitis rate, but it came down at once when football was stopped.

Mr. H. M. **Hanschell** spoke of the good effect of simple rest in bed and the keeping up of gentle warmth, such as by the application of thermogene wool. The two-glass urine test he did not regard as of real value as showing posterior urethritis, unless it was so severe that there was a coincident cystitis.

Dr. B. B. **Sharp** referred to a case of what appeared to be anterior urethritis, which, after washing out until the fluid became clear, and the prostate and vesicles seemed normal, was regarded as cured. Three days later the patient slipped in his bath and injured his testicles, and when next seen by the speaker, after having rested in bed, the man had posterior urethritis. Possibly the infection had spread via the lymphatics from the anterior urethra to the epididymis, and the posterior urethra had been infected from the epididymis and perhaps by lymphatics.

Mr. E. R. T. **Clarkson** said that although this was not an ethical society, there was one feature of the discussion which he would like to ventilate. It was as to whether, when consulting his medical adviser and found by him to have dual epididymitis, such a patient should, without putting the question, be informed that there was a danger that he might be sterile in marriage, and that a prospective wife should therefore be advised as to that possibility. Did the meeting agree with him that the subject was sufficiently important, as regards both parties, for that course to be justified ? To allow the prospective wife to enter into a union with such a man in ignorance seemed scarcely to be " playing the game." If such a man did marry, without himself knowing he was liable to be sterile, he could, it seemed, justly feel he had a moral claim against his medical adviser for not having done his duty in this respect. If the patient asked his doctor the direct question, the course was clear and the matter much simplified.

Mr. C. **Mills** said it was his view that the medical man should in every such case point out the danger of sterility, whether directly asked by the patient or not. It would not be fair to allow such a man to enter into marriage blind as to the likely consequences.

Dr. J. **Donald** spoke of the kind of cases in which the infection seemed to have been via the lymphatics, not from the posterior urethra.

Dr. M. **Korn** referred to a series of cases which were treated at London Hospital, under Mr. H. Lett, by the injection of contramine for epididymo-orchitis. There was definite benefit from this method, for they recovered in about a fortnight, or in half the time compared with the cases in which it was not used. He had found that a prolific cause of epididymitis was the use by the patient of strong solutions of such fluids as permanganate.

The **President** was particularly interested in the question of trauma of the urethra and of the testicle in the matter of the prevention of epididymitis. During the war he had a unique opportunity of definitely associating a high onset of the condition with the playing of football, or the use of ungentle methods of treatment, such as having a strong head of fluid from placing the irrigation apparatus at too great a height ; also vigorous or too early massage of the prostate. He fully supported what Mr. Kenneth Walker said in regard to the usefulness of diathermy in the disease. He did not think one could be sure there was no pus in the posterior urethra, even after getting clear urine from the washing out, unless centrifugalising was carried out. With regard to the use of atropine, he related a case with very severe relapsing urethritis, with hard prostate and vesicles, which had immediate testicular swelling when manipulation was attempted, but the use of atropine the night before intended treatment enabled manipulation to be carried out without enlargement of the testicles.—Mr. **Kenneth Walker** briefly replied.

The Question of Neuro-Recurrence after Arsenobenzol Treatment.

The **President** gave a statement on the male cases of syphilis at the St. Thomas's Hospital V.D. centre, numbering 2638. In this number the cases with clinical symptoms of syphilis of the central nervous system were 168 (including 123 of tabes, 12 of general paresis, 6 of tabo-paresis). Of the 168, five had previously had arsenobenzol treatment, prior to the onset of the nerve symptoms, and he gave the details of these, which showed that only one patient had received the intensive course which was employed at the military hospitals during the war.

Gonococcal Infection from Sebaceous Follicle to Prepuce.

Mr. C. **Mills** showed a young man who, a week after exposure to infection, had a small " blind pimple " on the skin of his prepuce, and three days later had a second of these lesions, the skin being intact over both. There was no urethral discharge. The follicles were opened, and, as a routine, slides were made of the pus, which yielded pure gonococci. The urethra remained sterile.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

A **meeting** of the Surgical Section was held on May 23rd, Mr. R. A. **Stoney** being in the chair.

Mr. W. **Pearson** showed a case of

Atrophic Dermatitis Following " Trench Feet "

treated by periarterial sympathectomy. He said that this condition was a rare sequel to trench feet ; this was the second case he had seen. The trouble had started in 1915 with swelling and pain in the feet, since then there had been recurring attacks of vesication of the dorsum of the feet associated with coldness and tingling. He had performed periarterial sympathectomy over three weeks ago, and so far the patient had greatly improved, but it was too early yet to know whether a cure had been effected. The patient said his feet had been quite warm since the operation, and he had not any vesication. It was a very simple operation to do. In the other case which Mr. Pearson had seen the patient had had a great deal of local treatment without benefit, and so he came to the conclusion that surgery was the only possible chance. A dermatologist who was consulted called the condition atrophic dermatitis, and said it was a condition resembling X ray burns, being very unresponsive to treatment. Mr. Pearson had operated and the patient was completely cured.

The **President** thought that Leriche's operation would be of great help in many cases, as it was apparently a possible cure for such conditions.—Mr. H. **Stokes** suggested the applicability of this operation to chronic ulcers.—Mr. **Pearson**, in replying, said that Leriche's operation was at first advocated not for vascular conditions, but for reflex contractions and paralysis, in which the wounds occurred in the neighbourhood of large blood-vessels and nerves. He personally did not think that the operation would cure such cases. It had been used with benefit in the treatment of callous ulcers.

Mr. A. K. **Henry** read a note on an investigation of a

Mechanism of Sudden Death in Cerebral Tumours,

illustrated with lantern slides. He dealt in particular with tumours of the posterior fossa, giving rise to increased intracranial pressure. It had been known for nearly a century that when intracranial pressure was increased the brain tended to herniate through all possible openings. Notable among these was the foramen magnum, and the hernia here consisted of the part of the cerebellum known as the tonsils and portions of the biventral lobes. In two of Cushing's cases the hernia, which he called the foraminal pressure cone, reached the level of the posterior arch of the atlas and compressed the medulla. The patient's life was saved in each case by resection of the arch. The fact of herniation and its results were beyond question. Mr. Henry had investigated the mechanism which allowed this hernia to occur in the hope that its comprehension might suggest means of preventing its calamitous effects. He had noted himself, and it had been noted by others, that death might occur in these cases when they sat up. The patient, feeling comfortable and well in the recumbent position, sat up in bed and fell forward dead as if he had been shot. He drew attention to the fact that the act of rising from the recumbent posture was begun by bending the head forwards. His conclusions were based on two simple observations and experiments. First, if one looked in the dissecting-room at the floor of the skull, after the skull cap and brain had been removed, while the cord and spinal canal were still intact, and, if one moved the head and neck backwards and forwards, the cord worked like a piston in the upper part of the spinal canal. When the parts were flexed forward the cord appeared to retire down the canal; when the head and neck were bent back the cord tended to project up through the foramen magnum. What really happened was that the cord was like a stationary piston, while the canal moved and shortened over it. When, however, the cord had not been cut and the brain was in position, the superimposed brain-stem prevented the upward projection of the cord at the foramen magnum, and its progress being checked, the cervical portion of the cord became sinuous. At the same time the brain-stem, which in the forward position of the head and neck was closely applied to the floor of the skull and, what was more important, to the odontoid process, moved when the parts were extended slightly back from the skull floor and the odontoid tip. If a sagittal section of the head were made in the cadaver, any pressure with the thumb in an outward direction upon the cut surface of the cerebellum, when the head was bent forwards, forced the brain-stem against the odontoid and the floor of the skull; when the head and neck were retroflexed it was impossible in the normal subject to force the brain-stem by this means into the same close contact with the bones. When the head and neck were flexed forward the most caudal part of the cerebellum lay directly over a space shaped like a funnel. This space, which was the cisterna magna, was largest when the head was bent forward and left most room for cerebellar hernia. When the head and neck were thrown back the size of the cisterna magna was disminished. The caudal part of the cerebellum was no longer poised over the opening of the foramen magnum, but lay over the atlas arch. The second observation was that if the brain was removed from a cadaver, the cord and spinal canal being left intact, and if water was poured through the foramen magnum until the spinal subarachnoid space was full, backward movement of the head and neck caused the level of the fluid to rise into the skull, while with forward flexion the water level fell. This meant that when the head and neck were forward the capacity of the subarachnoid space was increased in the spinal canal. If this occurred suddenly in a case where the pressure in the posterior cranial fossa was high, the potential vacuum formed below the cerebellum at the moment when it was poised directly over the foramen magnum would favour its prolapse. Subtraction of fluid by lumbar puncture was notoriously dangerous in cases of tumour of the posterior cranial fossa. The mechanism considered suggested that the position of the patient's head and neck during and after these interventions might determine his survival or death. Mr. Henry discussed the prevention of sudden death in the light of his findings.

Discussion.

The PRESIDENT said that they had all been aware for a long time of the danger of lumbar puncture in cases of increased intracranial pressure, and Mr. Henry had now explained how that danger arose. He would like to know, however, if Mr. Henry thought that death was due to direct injury of the anterior surface of the medulla or to injury to the cerebellum behind.—Dr. J. SPEARES said he had seen one case of cerebral tumour in which sudden death had occurred, and he thought Mr. Henry's ideas might explain the accident which had happened. He regretted that Mr. Henry had not discussed the reason why such patients got increased intracranial pressure, and why small tumours give rise to increased intracranial pressure. He wondered if a frontal tumour would produce the same result as Mr. Henry had described.—Mr. PEARSON said he thought one was rather apt to forget the effect which the dura septa had in dividing the skull into different parts.—Mr. HENRY, in replying, said that any œdema which occurred round the tumour would help herniation very much, but why a small tumour should cause increased intracranial pressure it was hard to say, unless it had an irritative action. Many tumours caused focal symptoms, without causing actual destruction of the brain, and if the pressure were evenly distributed through the brain it was very hard to say why in these cases focal symptoms were found.

Mr. SETON PRINGLE read a paper on

Aseptic Resection of the Colon.

He first reviewed the work which had been done on this subject, describing the methods which Halstead, Highsmith, Schoemaker, and Fraser had employed. Mr. Pringle's method differs only in details from those of Highsmith and Fraser. When the bowel has been mobilised and the vessels ligatured, he applies a large crushing clamp with blades one inch wide to the intestine at the point above the growth selected for division. He then places a narrow fine forceps on the crushed portion close up to the end which is subsequently to be anastomosed. He treats the gut below the growth in a similar manner, and, on proceeding to carry out the anastomosis, the two fine clamps are approximated and the ends of the intestine united by mattress sutures, the clamps being left in position and thus controlling the bowel until the encircling line of suture is almost completed. He claimed that in this way there was less risk of infection occurring than in any of the methods previously described, and, also, that the internal shelf, or partial diaphragm left in all these operations, is less following his method. He had carried out the operation described in three cases of partial colectomy for cancer, and each made an excellent recovery without the slightest sign of local or general infection.

The PRESIDENT said that although Mr. Pringle's conception of performing colectomy without exposing the opening of the bowel during the operation was not original, his method was superior to any methods previously described. It was apparently very simple and required no special instruments. It was important to note that the intestine was divided through the crushed portion, so that there was no need to interfere with the mucous membrane. If the needle once went into the interior of the bowel the whole operation was wasted, but by Mr. Pringle's method this could not occur. He asked if Mr. Pringle had experienced any difficulty in performing the operation in cases where it had been necessary to join the small intestine to the large intestine.—Dr. D. K. MILNE-HENRY described a special form of ligature which she employed in these cases.—Mr. PEARSON asked whether Mr. Pringle had ever experienced any difficulty in withdrawing the forceps, or if they slipped off easily.—Mr. A. K. HENRY said that the diaphragm in Mr. Pringle's method was reduced to the smallest possible terms. He referred to the danger of crushing clamps cutting the bowel; he knew of four cases in which death had occurred owing to this.—Mr. A. CHANCE said that he had adopted Mr. Pringle's method. The application of the fine closing clamps required to be very accurate, it must go down just to the junction of the gut with the mesentery so as to close the opening, and yet no further. It was necessary to take a very wide bite of gut on either side to cover the clamp ends.

Mr. PRINGLE briefly replied.

Reviews and Notices of Books.

A Text-book of Pharmacology and Therapeutics.

Or the Action of Drugs in Health and Disease. Eighth edition, thoroughly revised. By Arthur R. Cushny, M.A., M.D., LL.D., F.R.S., Professor of Materia Medica and Pharmacology in the University of Edinburgh. With 73 illustrations. London: J. and A. Churchill. 1924. Pp. 707. 24*s.*

It is surprising to note that it is already six years since the seventh edition of this well-known text-book was published, but after even a conservative review of discoveries made in the time that has passed, it must be granted that there is sufficient warrant for a new edition. As the author points out, the rapidity of progress is not always recognised; thus, since the 1903 edition the space allotted to remedies for specific diseases in the therapeutic index has increased five-fold. The chapter on the action of digitalis has been considerably extended to give a lucid account of the irregularities which may arise under the influence of digitalis therapy. The use of quinidine in auricular fibrillation is described, and the difference between its mode of action and that of digitalis explained. Under the heading of ergot, the author has not considered the properties of histamine and tyramine, but has confined attention to the specific alkaloid ergotoxin (or ergotamine). This treatment should help to clarify the existing confusion, for the presence of histamine and tyramine in ergot preparations has led many to the view that they are essential constituents rather than accidental contaminations of such preparations. Rather curiously, histamine is described in a section together with anaphylaxis, because of the similarity of the symptoms produced by histamine poisoning and anaphylactic shock. Although Cushny makes it clear in the text that the resemblance ends here, one cannot help thinking that some students will be misled by the juxtaposition in the title of the chapter. Local anæsthetics are described in such a way as to draw attention to the substitutes for cocaine; stress is laid on the value of eucaine for application to mucous membranes, and of novocaine and tropacocaine for injection. Finally, chapters on the vitamins and on the insulin treatment of diabetes complete the list of the main new features of the edition.

It is, in some respects, a pity that the author only allows his personality to escape in small print; we think that his remarks on organotherapy, were they known to all students, might have a considerable influence on their future practice. For example, he says: "The theory on which many of these (organ extracts) have been evolved, shows little advance upon the belief of the savage that the courage of the lion may be acquired by eating the animal's heart." The criticism is justifiable. One of the difficulties of modern research consists in keeping abreast of other adventures in different fields; but while this is a difficulty, to maintain adequate contact with the past is almost an impossibility. Many good papers are read and their contents become generally known, but probably for each of these there is another which is forgotten, when the author's work is lost. It is a particular merit of Cushny's text-book that it preserves for us a connexion with a great many papers full of important observations written 30 or 40 years ago, and in this way contributes very materially to continuity in research and the avoidance of repetition. On the other hand, for the clinician the experimental evidence for the value of every therapeutic agent is presented more carefully than anywhere else, and a clinician's success in treatment may depend on his knowledge of that evidence more than on any one other factor.

No attempt is here made to summarise the contents of what is a monumental work—all doctors should possess it.

The Parathyroid Glands in Relation to Disease.

By H. W. C. Vines, M.A., M.D., Fellow of Christ's College, Cambridge, Foulerton Research Student of the Royal Society; late Beit Memorial Research Fellow. London: Edward Arnold and Co. 1924. Pp. 128. 10*s.*

Many of those interested in endocrinology must have felt the desirability of having an impartial and critical review of the position of the parathyroids in relation to disease. Dr. Vines's book supplies to some extent such a need. The physiology and pathology of these organs are fully discussed, especially in their relation to calcium metabolism. There appears to be good evidence that the parathyroids do play a part in the calcium exchanges of the body. To what extent calcium metabolism and the parathyroids come into play in the causation and treatment of such disorders as varicose ulcers, gastric and intestinal ulcers, and various infective conditions, those who read the book must judge for themselves. The impression left on us is that these matters are as yet unripe for decision.

Cystoscopy.

Kystoskopische Technik. By Eugen Joseph, A.-O. Professor at the University of Berlin. Berlin: Julius Springer. 1923. Pp. 221. 15*s.*

This is one of the most satisfactory of the many German text-books on cystoscopy. It is profusely illustrated and the coloured illustrations reach an exactness of reproduction, both by artist and printer, which is seldom attained. Embodied in the book is also a large collection of pyelographs. The compilation of this work can only have come from the careful observation of a large number of patients; the text as well as the illustrations give abundant evidence of this. Whether the author writes about appearances characteristic of tuberculous infection of the bladder, the value to be attached to kidney function tests, the use of diathermy, or other urinary topics, his remarks are always worth consideration, and the book forms a useful guide to the cystoscopist.

Blood Pressure.

Cause, Effect, and Remedy. By L. T. Barker, M.D., and N. B. Cole, M.D. London and New York: D. Appleton and Co. 1924. Pp. 154. 5*s.*

In this little book, written primarily for the layman, the authors give in simple non-technical language an excellent account of the physiology and pathology of blood pressure. After dealing with the factors responsible for the maintenance of normal blood pressure, they proceed to discuss hypertension and its causes, emphasising the fact that no single factor is to be held responsible and showing how over-feeding, over-drinking, and, above all, over-working all play their part in the production of this increasingly prevalent malady. In a chapter entitled "What to do," they indicate clearly how high blood pressure, and incidentally, we might add, many other diseases, may best be avoided. It is fortunate that a book of this type should come from such an authoritative source, and we can strongly advise every practitioner to read it, feeling sure that he will find there not only much useful information but also the best means of imparting it to his patients.

Le Syphiloïde du Jutland.

By Prof. Edv. Ehlers, Médecin en Chef de l'Hôpital Communal de Copenhague. Paris: Masson et Cie. 1923. Pp. 85. Fr.9.

This little brochure was produced on the 150th anniversary of the first legislation for the free treatment of venereal disease in Denmark. It sets down from the beginning in 1773 to the present day the royal rescripts, &c., on this subject. The idea of free treatment for venereal diseases, and at the same time compulsion of the sufferer to have treatment, originated in Denmark with Johan Eichel (1729 to 1817), and to his efforts the first legislation was due. The author shows that in its earlier epidemic form syphilis in Denmark caused frequently destruction and mutilation of the nasal bones. This had the effect of alarming the lay authorities and doubtless helped the passage of legislation. At the present time mutilation of the nose is infrequent in Denmark, because as a result of the measures taken in the last century and a half the disease is now a venereal malady and never assumes epidemic form. Prof. Ehlers believes that the disease attacks the nasal bones preferably in those with primary oral infection, and only supervenes when the disease is not recognised or treated till the nasal lesion begins; this happens early in the primary oral infections common in the epidemic form of the disease. He finds support for this view in the history set down in this little book.

The pamphlet is a most interesting note on syphilis in a peasant community.

PHYSIOLOGY.

Lehrbuch der Physiologie des Menschen. By W. TRENDELENBURG (Tübingen) and A. LOEWY (Davos). With collaboration of other writers. Leipzig: F. C. W. Vogel. 1924. Pp. 789 + xiv. 24*s*.

THIS book represents the fourth edition of what was known as Loewy and Zuntz's Lehrbuch, and should continue to hold the high place among text-books of physiology which that publication deservedly gained. The name of Prof. W. Trendelenburg, which replaces that of the late Prof. N. Zuntz, is highly regarded, and the publishers are fortunate to have secured his services as editor. For those to whom the work is not yet familiar, we can recommend it as one of the most complete and up-to-date text-books on physiology now current. The various chapters are written by recognised authorities on the particular branches of physiological work. The consequence is that the book is kept well up to date in all branches; physiology is now such an extensive subject that this method seems to be the only one to be relied upon. It is unfortunate that since the publication of Schäfer's Text-Book of Physiology no serious attempt has been made to bring out a joint text-book in the English language. Those able to read German, however, can console themselves adequately with Trendelenburg and Loewy's really fine edition.

WHEELER'S HANDBOOK OF MEDICINE.

Seventh edition. By WILLIAM R. JACK, B.Sc., M.D., F.R.F.P.S. Glasg., Physician to the Glasgow Royal Infirmary; Lecturer in Clinical Medicine in the University, Glasgow. Edinburgh: E. and S. Livingstone. 1924. Pp. 692. 12*s*. 6*d*.

DURING the four years that have elapsed since the publication of the last edition many changes have occurred in our outlook upon medicine. The opportunity has been taken of incorporating the more important of these advances in the new edition of this book. This has involved a rearrangement of certain of the subjects, and others have been rewritten or expanded. Certain new articles are added in the section dealing with diseases of the nervous system; they include a description of encephalitis lethargica and progressive lenticular degeneration. "Wheeler and Jack" is a household word amongst medical students. Although the manual has grown since we first knew it, it has not become too unwieldy to carry about for reference during clinical hospital work. The information which it contains is most reliable, and we feel sure that its reputation will continue unabated.

A MANUAL OF THE PRACTICE OF MEDICINE.

Prepared especially for Students. Eleventh edition. By A. A. STEVENS, A.M., M.D., Professor of Applied Therapeutics in the University of Pennsylvania; Visiting Physician to the Philadelphia General Hospital. London and Philadelphia: W. B. Saunders Company. 1924. Pp. 645. 18*s*.

THE eleventh edition of Dr. Stevens's manual for students has been entirely revised, reset, and brought up to date, and additional subject-matter included dealing with such conditions as thrombo-angitis obliterans and toxic goitre. In a book of this size some important subjects are necessarily treated briefly, but the text has been fairly apportioned and a clear and readable account of the essentials of medicine is presented. Over 70 pages are devoted to diseases of the skin, and here, as elsewhere, the text is liberally interspersed with prescriptions, a feature which invariably appeals to students. On the whole, the book compares favourably with other books of similar size and will prove useful for rapid revision for examinations.

A DESCRIPTIVE ATLAS OF RADIOGRAPHS OF BONES AND JOINTS.

By A. P. BERTWISTLE, M.B., Ch.B. Leeds, Resident Surgical Officer, General Infirmary, Leeds. Bristol: John Wright and Sons, Ltd. 1924. Pp. 198. 17*s*. 6*d*.

THIS is a collection of 299 silhouette radiographs of diseases of bones and joints. This method of presenting radiographs was devised by the author and the process is explained in the first part. A very useful feature of the book is the collection of X ray appearances of normal bones and epiphyses. There is great variability in the times of appearance of centres of ossification, which induced the author to add this section to the book. Pathological photographs are arranged in four sections—fractures, diseases of bones, affections of joints, and miscellaneous conditions. Almost without exception, they are representative of the usual appearances seen and very few could be omitted without the usefulness of the book being impaired. None of the photographs have been borrowed from other works, so the book becomes particularly useful as a series of photographs obtained by routine work in a general hospital. The reproductions have been very carefully and beautifully made and they show the structure of the bones almost as clearly as original plates.

CARE AND FEEDING OF INFANTS AND CHILDREN.

Third edition. By WALTER REEVE RAMSEY, M.D. London: J. B. Lippincott Co. 1923. Pp. 290. 10*s*. 6*d*.

IN addition to the various questions relating to growth, feeding, sleep, clothing, and general hygiene, the author discusses a large number of the commoner diseases of children, devoting, indeed, nearly half the volume to a consideration of these abnormal conditions. Dr. Ramsey has admirably succeeded in his aim of giving the trained nurse, for whom the book is designed, the kind of information which will be useful to her. In the chapter on diseases of the respiratory tract a welcome innovation is the protest against the use of pneumonia jackets in pneumonia and bronchopneumonia when the temperature is running high, these appliances simply keeping up the pyrexia by preventing the necessary loss of heat. The use of alcohol compresses in their stead is advised. No reference is made in the chapter on the infectious diseases to the prophylaxis of measles by the subcutaneous injection of serum from a convalescent patient.

The author does not attempt to say anything new upon his subject when novelty is the only argument in favour. The book, which is attractively written and unusually well-illustrated, is likely to remain one of the best manuals of its size for nurses, and to them we heartily commend it.

HEALING.

By the Rev. M. R. NEWBOLT. London: Society for Promoting Christian Knowledge; New York and Toronto: The Macmillan Company. 1924. Pp. 96. 2*s.*

IN this short book we have psychic healing introduced in its implications from the religious point of view. In a chapter on Holy Unction, a form of psychic healing which did not receive the unanimous endorsement of the recent Lambeth Conference, the author points out that, while the Eastern and Western Churches agree that the healing of spiritual infirmities is the first object of this sacrament, bodily healing being a secondary though real part of its content, there has recently arisen in the Anglican Church a use of Unction hardly to be distinguished from faith-healing. Mr. Newbolt holds the view that faith-healing and the sacrament of Unction are two separate things. In regard to psychic healing and medicine, the author, while believing that "in an ideal world the doctor and the spiritual healer would both work together, or, better still, their functions would be combined in the same man," deprecates any conflict between medicine and the church. An appendix deals briefly with Ecclesiastical Miracles, Lourdes, Christian Science, and the methods of Coué.

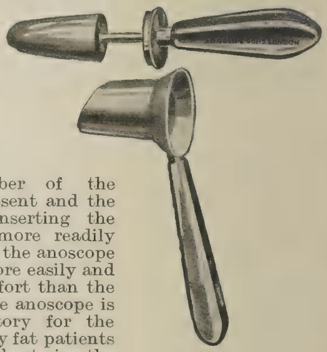
JOURNALS.

BRITISH JOURNAL OF SURGERY.—The April volume contains Sir D'Arcy Power's twelfth eponym on Teale's amputation.—Hamilton Bailey discusses injuries to the kidney and ureter, as seen in 135 cases at the London Hospital in the past 21 years. He shows that whereas the prognosis of uncomplicated injuries to one kidney is extraordinarily good, cases in which other organs are injured as well are usually fatal.—Sir Hamilton Ballance reports a case of spontaneous fracture of the humerus due to an intermedullary capillary angioma. The histological report by the late Prof. Shattock is given.—C. A. Moore, G. Hadfield, and L. E. Claremont review the surgical, pathological, and dental aspects of an epithelial odontome as illustrated by a case under their care.—An account is given of a visit to some of the surgical clinics of Stockholm, and are described: the clinic of Prof. Gösta Forssell at the Radium Institute, that of Prof. Jacobaeus at the Serafimer Hospital, and the work of Prof. Einar Key, and of Prof. Waldenström was also seen.—R. C. Shaw contributes a study of rhizotomy for intractable pain, and he believes that many stump neuralgias may be cured by the division of the dorsal and ventral roots, that in tabes the results completely justify the operation, and finally he draws attention to the brilliant results following the section of the antero-lateral column of the cord.—Twenty-five cases of early acute appendicitis were examined by L. S. Dudgeon and P. H. Mitchener by both bacteriological and pathological methods. The urine and the blood were examined with a view of determining any concomitant infection. Among other results they found fats present in the lumen, mucous lining, in the gland cells, and in the lymph roots of the appendix wall in the quiescent cases, and they suggest that fat absorption occurs from the lumen.—R. St. Leger Brockman's Hunterian lecture on drainage in acute appendicitis summarises the modern opinion on this subject. He points out how easily the peritoneum can defend itself, and yet how incapable of resistance are the muscles of the abdominal wall. He therefore advises closure of the peritoneal cavity with rubber tissue drainage of the muscular layers.—A. Pinoy describes a specific type of blood picture seen in cases of metastatic tumours of bone, and divides them into pseudo-pernicious and pseudo-leukæmic types.—C. A. R. Nitch describes at length that interesting condition known as cystic pneumatosis of the intestine. He believes that they fall into two groups—viz., the commoner cystic and mechanical variety and those due to infection by gas-producing organisms.—R. Lawford Knaggs divides cases of osteogenesis imperfecta into four clinical groups—viz., those occurring in the fœtus, in the infant, in adolescents, and in middle or late life. He points out the hereditary tendency of the condition, and its association with "blue sclerotics." He describes a typical histological picture of the bones, and finally discusses the pathogenesis and treatment.—W. Girling Ball gives an admirable account of the treatment of simple papillomata of the bladder by fulguration, and his paper is most beautifully illustrated by coloured drawings of the cystoscopic appearances.—The following rare or obscure cases are published: (1) J. H. Mather, a pin found in the appendix; (2) H. Nockolds, volvulus of the stomach; (3) C. P. G. Wakeley, a case of carcinoma of the breast, dying 13½ years after operation from diffuse secondary deposits; (4) A. J. Blaxland, intussusception of the sigmoid 3½ years after an intussusception of the appendix; (5) C. P. G. Wakeley, acute intussusception in a bilocular femoral hernial sac; (6) M. B. Hannay and R. F. Young, carcinoma of the solitary kidney.

New Inventions.

AN ANOSCOPE AND SYRINGE FOR THE "INJECTION TREATMENT" OF HÆMORRHOIDS.

THE anoscope is an anal speculum which has been made to my specification for use instead of the proctoscope or rectal speculum in the injection treatment of hæmorrhoids. It is 1½ in. long, but when the obturator is in position it measures 3 in. The advantages of the instrument are: (1) By its use the piles are in the correct position for injection, or at most it need only be withdrawn half an inch; (2) a bigger field is brought into view than is possible when the proctoscope is used, and the exact size and number of the hæmorrhoids present and the best site for inserting the needle can be more readily ascertained; (3) the anoscope can be passed more easily and with less discomfort than the proctoscope. The anoscope is not so satisfactory for the treatment of very fat patients as owing to its short size the buttocks overlap it; a proctoscope with an oblique opening and smooth unraised edge—i.e., the same design as the anoscope—which also has been made for me, will be found more suitable in treating this type of case. The syringe for the carbolic solution is somewhat similar in design to Dawson's dental syringe, but is made of glass with metal jointures, after the fashion of the "Record," so that one can see the solution and make sure that no bubbles or foreign matter are injected with it. It is graduated in minims to hold 40 minims, and special wide-bore needles, ½ in. long, are supplied with it. Very little claim for novelty could be made for this syringe except that it answers the query "What is the best type of syringe for use in the 'injection treatment' of hæmorrhoids?"



The anoscope and syringe are made by, and can be obtained from, Messrs. Arnold and Sons (John Bell and Croyden, Ltd.), 50–52, Wigmore-street, W. 1.

P. KENNEDY MURPHY, M.D. Dub.

Bedford-square, W.C.

THE LANCET.

LONDON: SATURDAY, JUNE 7, 1924.

THE MEMORANDUM ON ENCEPHALITIS LETHARGICA.

THE existing prevalence of encephalitis lethargica, or epidemic encephalitis as this disease is more often called, has increased the interest concerning this comparatively new malady, an interest which is not restricted to the medical profession, but which has spread to the lay press where it is now referred to under the odd description of "sleepy sickness." A brief but at the same time authoritative compendium on a prevailing malady is always welcome, and the Ministry of Health have done good service in issuing a short memorandum[1] at the present time, based on the previous document of 1921, but revised and extended in accordance with recent knowledge and in the light of observations made during the epidemic outbreaks of this year. Primarily intended for local authorities and for medical officers of health, the memorandum is one which may be commended to busy medical practitioners who have neither the opportunity of consulting nor the leisure to read more comprehensive treatises, such as Prof. ARTHUR J. HALL'S Lumleian lectures [2] on epidemic encephalitis, which appear this week in book form.[3] After referring to possible appearances of epidemic encephalitis in the past, the memorandum briefly traces the history of the disease since 1917, the year when it first became recognised as a clinical entity. Its present distribution is worldwide, and most of the countries of Europe, Asia, America, and Australasia have been affected by it in greater or less degree. This extensive occurrence during the last five years argues much for the evolutionary theory of the malady. We are too apt to forget that evolution proceeds ever onwards, and that side by side with the elimination of old diseases, new diseases may appear or reappear after long absence through the originating of a species of organism hostile to man or, alternatively, by reason of the taking on of inimical parasitic function by a previously harmless saprophyte. On the recognition of the disease notification was promptly required by the Central Health Authority in England and Wales. As a result our figures for the incidence of the malady are the most complete of any country. In the five-year period 1919–23 the following cases were notified: 1919, 538 cases; 1920, 914 cases; 1921, 1470 cases; 1922, 454 cases; and 1923, 1025 cases. During the first and second (uncompleted) quarters of the present year the unprecedented number of 2468 cases has been notified (provisional figures). This epidemic outbreak appears to be confined to the British Isles. For the week ending May 24th, 1924, the number of notified cases shows a slight diminution on the provisional figures, 261 cases having been notified, as against 282 in the previous week and 290 in the week ending May 10th. The figures for London have fallen from 43 to 28. It seems possible that the diminution is really greater than appears from the figures, owing to the large amount of public and medical attention which has been given to the epidemic and consequently to the recent identification of slight cases which would not otherwise have been diagnosed. The cases remain scattered, indicating that the wide diffusion of the infection continues.

In spite of much laboratory work the exact identification of the causal organism still eludes the pathologist. The memorandum pays a tribute to the important experimental work of MCINTOSH and of LEVADITI, but emphasises that much further work is required. Investigations on material obtained from the present epidemic are proceeding under the auspices of the Medical Research Council, and are linked up with researches on the whole question of filter-passers and herpetic viruses. It is only by comprehensive attacks of this character that success is likely to be obtained. A short general description is given of the clinical forms of encephalitis lethargica, and reference is made to the clinical alterations in type seen in the epidemic of 1924. "The malady," the memorandum states, "is on the whole less severe, and in many cases the prodromal period appears to exceed the usual seven days. The onset is often ascribed to influenza, and a fortnight or more elapses before the definite signs of encephalitis are manifest. Patients do not remain for lengthy periods in profound stupor or coma, and some have made an unusually rapid recovery; catalepsy is rare." Myoclonic forms are common, and fibrillary twitchings of the abdominal muscles are not infrequent. Signs of hyperactivity of the brain—sleeplessness, delirium, excitement, myotatic irritability—predominate. These changes in clinical characters were drawn attention to by STALLYBRASS[4] as prevailing in Liverpool last year. The French and Italian records show that as early as 1919 such variations had occurred to an appreciable extent on the continent.

The Ministry of Health consider that the case-mortality of encephalitis lethargica since 1917 may be given as between 20 and 50 per cent. These are wide limits and the higher figure is probably the more accurate. On the deaths so far reported in the present epidemic, the case-mortality has varied in different cities from 12 to 21 per cent. of the notified cases. It is too soon yet to make a correct estimation. Stress is laid in the memorandum and in the covering circular on the sad after-effects of epidemic encephalitis, the mental symptoms, the Parkinsonian syndrome, excito-motor and other sequelæ. The diffusion of knowledge on this question is highly desirable, as the sequelæ are of both neurological and medico-legal importance. The original acute attack may be so mild as to pass disregarded, and it is not until alterations in conduct or profound nervous manifestations arise that the true condition is recognised. It is held that the degree of infectivity of encephalitis from person to person is of a low order. Nevertheless, the existence of multiple cases of the disease in the same household, as well as in institutions, must not be lost sight of, and the study of these intensive outbreaks is most likely to be informative as to the channels of spread of the disease. After referring to treatment and abortive mild or "transient" cases, the remainder of the memorandum is devoted to the action which it is desirable for medical officers of health to take on receipt of notification or on learning of suspected cases—a brief chapter in applied hygiene, which we print in full elsewhere.

LEAD AND CANCER.

Prof. Blair Bell's work on the effect of lead in preventing the growth of tissues generally and especially that abnormal method of growth which results in cancer will be familiar to readers of The Lancet of Feb. 9th, 1924. In an address to the North-Western Branch of the Society of Medical Officers of Health, which is published in the June number of *Public Health*, he returns to the subject in a fresh way. After pointing out that he regards malignancy as an atavistic reversion of somatic cells to a condition where they have many of the properties of chorionic epithelium, to which lead is particularly poisonous, he draws attention to the rarity of cancer among those exposed to lead poisoning. The general technical manager of the United Alkali Company is responsible for the very interesting statement that cancer is unknown among the large number of "chemical plumbers" employed by the firm. These men are engaged in making and repairing vitriol chambers, acid cisterns, and the like, fusing the seams with an oxy-hydrogen blowpipe and so being rather freely exposed to volatilised lead; they suffer from plumbism, but not from cancer. The district secretary of the United Operative Plumbers and Domestic Engineers' Association, through whose hands all medical certificates had passed for 25 years, confirmed the absence of cancer in this particular occupational group. The statistics are not, as the author freely recognises, satisfactory or conclusive; they do not, for example, take into consideration age or, which is often of special importance in industrial data, previous and subsequent occupation. The same criticism applies to some further figures relating to the incidence of cancer in towns with lead in the water-supply, and to the increase of cancer which is associated with a decrease in plumbism—the latter being, of course, a form of numerical analysis open to great fallacy. But the facts are put forward in a tentative way to justify the more complete investigation which the author has not been able to carry out. The case of the chemical plumbers certainly seems to be worth further inquiry. The address concludes with an appeal for more activity in the campaign for the prevention of cancer, and here Prof. Blair Bell is less precisely constructive than we could have wished. If the 10,000 deaths per annum from cancer of the breast and uterus are, as he says, almost entirely preventable, the exact lines of preventive action are worth defining. But he rightly points out that the discovery of the cause of disease does not necessarily lead to its control—e.g., tuberculosis—and without at present advocating a universal mild plumbism, he indicates soot, hot drinks, and parturition per vaginam as contributory causes which demand careful thought.

◆

THE YOUNG OFFENDER.

The establishment of Children's Courts was a wise step, involving the recognition of the importance of separating such as are still at an exceptionally plastic and receptive age from others whose influence or example might have a disastrous effect upon them. It eliminated the risk of publicity, and recognised the desirability of children being dealt with by those who have special sympathy and understanding of the young. But there is a growing feeling that the present system does not go far enough. While the old idea that delinquency must be dealt with by punishing somebody, whether it be by fining the parents or birching the offender, still has great influence; nevertheless, the idea is slowly coming home to many that, instead of being content with primitive and rule-of-thumb methods, it would be wiser to devise some definite means for inquiring into the causes, for dealing with those causes, and eradicating them. It is easier for the medical profession to accept this point of view than it is for the legal. Medical psychologists are concerned with the individual; they regard misconduct as the expression of a state of mind which is abnormal in its social relationships; they seek to ascertain the causes of this state, and if possible to deal with them. But lawyers are not concerned primarily with the individual, but with the protection of the community, and are inclined to think that this can be attained by the deterrent effect of punishment, alike on the individual and the community. Without going fully into this side of the problem, it may be said that the record of the large amount of crime committed in the eighteenth century, when severe penalties were imposed for comparatively minor offences, raised doubt as to the deterrent effect on others, while crime has continued to diminish as punishment and prisons have become more humane in recent years. So, too, while punishment often has a restraining influence on the individual, it is clear that in certain cases an individual's state of mind may be such as to render him undeterred by punishment; indeed, punishment may have the opposite effect. Years ago insanity was recognised as constituting a state of irresponsibility, for which treatment, and not punishment, was required. In 1913 it was enacted that mental defectives also, who committed offences, should be treated and not punished. There are other less well-defined conditions, such as incipient insanity, degrees of dullness not constituting actual mental defect, and cases of mental conflict, in which it is essential that a report on the psychological state should be placed before the court, if justice is to be done. Nor must it be forgotten that in recent years many reports have been published of the complete change in conduct and moral character that has sometimes followed an attack of encephalitis lethargica in a young person. All physicians, too, would agree that abnormal physical conditions sometimes constitute an important factor in juvenile delinquency, both in themselves and also in fostering a feeling of inferiority. Such considerations make it reasonable to ask that every juvenile delinquent should be examined by a medical practitioner, who is also a psychologist, before he is punished or put on probation. In the Children's Court a psychological examination is all-important. It is only possible to judge a child's behaviour, his responsibility for action, and his knowledge of the consequences of any particular action in terms of his "mental age." A child of 12, with a mental age of 6, will probably choose companions of 6 years old, and his behaviour will be more or less that of a 6-year-old child.

Mental defect, in its higher grades at least, can only be diagnosed by the expert with long experience. The magistrate who thinks he can recognise it himself at a glance has only idiots and imbeciles in his mind's eye, and does not know that the courts are still sometimes overlooking not only the feeble-minded but even actual imbeciles. The last report of the Prison Commissioners contains several examples of such procedures, which resulted in mental defectives being sent to prison, and subsequently left on discharge without care and supervision. Other reports show that even when an enlightened minority has provided the necessary machinery, magistrates sometimes do not realise the importance of making use of it. Five years ago Mr. GERALD BEASLEY, then chairman of the Birmingham Justices, introduced a scheme whereby an expert medical psychologist was available to examine any cases referred by the Bench. While this scheme has been used in many adult cases serious enough to be remanded in custody, the annual reports of the Birmingham Justices show that in each of the last two years only four of the less serious cases remanded out of custody have been put back for special examination. Yet this group includes all the cases in the Children's Court, of whom as many as 200 are put on probation in the course of a year. In many of these probation cases there must be physical and psychical abnormalities which ought to be dealt with first. There is the further consideration that the ordinary probation officer is often only able to classify a home as respectable or not, and has not had the training which would enable him to say that some respectable homes have an atmosphere in which it is impossible for the delinquent to develop satisfactorily. Such facts justify the recent action of the People's League of Health in sending a deputation[1] to the Home Office to state their opinion that, even where facilities are provided, the magistrates sometimes do not make proper use of them, thus depriving the child of his rights. Omission to do so is an economic blunder. All investigations into crime show the importance of the habitual offender, while all are agreed that the habitual offender nearly always begins as the young delinquent. The first offender, therefore, so far from being a case to be dismissed with a few words of well-meant advice, requires thorough investigation. Many inquiries have shown that, though it be his first appearance in court, he has often been on the wrong path for years, so that it may be the last opportunity of effective help. Those physicians who have had opportunities of seeing something of the workings of Children's Courts have recognised that unwise treatment of the child offender tends to produce deterioration of character, and to manufacture the habitual criminal. They have been impressed by the consequent moral and economic injury done to the community. They claim that an accurate knowledge of the mentality of delinquent children is essential if the children are to be dealt with justly and satisfactorily. They ask that in each case of actual delinquency the mental and physical history of the delinquent child should be investigated, and as complete a knowledge as possible obtained of his present condition, environment, and associations. Without such an inquiry and examination offenders may be punished when no punishment should be inflicted, and when, on the contrary, medical treatment is imperative.

It is not claimed that every case that comes into court must be examined. Offences against by-laws, such as playing football on the streets, should be treated in another way, requiring rather a social investigation into the facilities for play and recreation in the district. In the opinion of many they should be dealt with in the child's home rather than by bringing him into court. If a considerable group of delinquent children could be examined by medical experts, valuable information would be obtained as to the proportion of mental defectives among young delinquents. Classification of the others would show how far medical treatment was necessary, and give a useful guide as to the arrangements required for dealing with these cases. In Belgium the characteristics, peculiarities, and tendencies of delinquent children are observed by qualified persons and reported upon to the courts before the cases are adjudicated. There is no doubt that a fairly large group of young delinquents commit offences as a result of defective upbringing and faulty surroundings. They are not mentally abnormal, but living, as they do, in an atmosphere of selfishness, vice, immorality, and general depravity, they simply copy the example of those around them. Left where they are they fail to acquire any sense of moral obligation, and grow up with definite anti-social propensities, to become confirmed criminals. But there is clear evidence to show that if children of this type can be put into satisfactory surroundings they may become efficient and useful citizens. There is another group in whom the delinquency, even if of a serious kind, such as burglary, is largely due to a spirit of adventure, daring, and enterprise, which, when directed into healthier channels, may result in the development of valuable qualities. The sympathetic hearing accorded by the Home Secretary to the deputation from the League encourages the hope that the arrangements in the Children's Courts will be still further improved, and soon.

THE KASR-EL-AINY HOSPITAL AT CAIRO.

VISITORS to the Royal Academy may have been struck by the impressive architectural drawings in illustration of the projected rebuilding of the Kasr-el-Ainy Hospital in Cairo. In so far as that building was designed for a particular island site, unfortunately those pictures would seem to mean nothing. While the necessity for a new hospital as clinical and teaching centre has been admitted on all hands, it has for some time, we believe, been known that the site selected had not met with complete Egyptian approval, and in the end might not receive the buildings. This position now seems well confirmed, and the building must be indefinitely postponed if the announcement is accurate that a forfeit has been paid to the architects who had the contract. From a public as well as from a scientific point of view this is a matter of regret, for undoubtedly there is real need in Cairo for a new hospital and new medical school buildings. The delay is attributed to the need for economy, although the dislike of the King of Egypt to the project is well known. But a third reason for inactivity at the moment, and the one that must be operative in all shades of opinion, is the growth of the view that new hospital accommodation for Egypt is mainly needed in the provinces; for it is admitted that while there is only one hospital bed to about 15,000 inhabitants in the rest of the country, there is one bed to 800 in Cairo. This means that in the provinces the sick must often travel by river for as much as three days before reaching the Kasr-el-Ainy Hospital. As a matter of fact, both schemes require accomplishment; Cairo is in as great need as the country in general. In many ways, to bring hospitals to the people is a preferable policy, within limits, than to bring the people to a hospital, but there can be no doubt that a great centre for clinical treatment, scientific research, and medical education is required. Egyptian political affairs are in a transitional state, but scientific development among the Egyptians in respect of medicine will make them lean towards the scheme for a large scientific and clinical centre in Cairo, and an alternative site on the edge of the desert, in the neighbourhood of the capital, has already been spoken of. If this plan were carried out, subsidiary hospitals would be required in the crowded portions of the great city—there are over 800,000 people in Cairo to-day—and at these subsidiary institutions much emergency work and other weeding-out would be done, leaving for treatment at the centre only the suitable cases.

---

[1] The medical members of this deputation were as follow: Dr. E. A. Hamilton-Pearson, Dr. E. D. Macnamara, Dr. Christine Murrell, Dr. D. Orr, Dr. W. A. Potts, Dr. R. G. Rows, and Dr. A. F. Tredgold.

Annotations.

"Ne quid nimis."

THE BIRTHDAY HONOURS.

THE proportion of medical to lay honours in the long list which was published on the occasion of the King's birthday is an indication of the ever-increasing part which medicine plays in the affairs of the State, both at home and abroad, and is also a reflection of the growing recognition that the health of the people is an important factor in the spread of empire. In the Order of Merit appears the name of Sir Charles Scott Sherrington, President of the Royal Society, whose physiological reputation is world-wide; and among the baronets that of Sir Humphry Davy Rolleston, President of the Royal College of Physicians of London. A feature of the list is the inclusion of the names of Dr. Janet M. Campbell, Senior Medical Officer for Maternity and Child Welfare to the Ministry of Health, and Chief Woman Medical Adviser to the Board of Education, and Dr. Margaret Ida Balfour, Joint Secretary to the Dufferin Fund, the first of whom becomes a Dame and the second a Commander of the Order of the British Empire. Dr. John Utting, Lord Mayor of Liverpool in 1917–18, Chairman of the Finance Committee of the Liverpool Corporation, and Lieut.-Colonel T. J. Carey-Evans, I.M.S., Surgeon to the Viceroy, become knights. Dr. Malcolm Watson, of the Federated Malay States, also becomes a knight bachelor in recognition of his services in connexion with the prevention of malaria. Colonel Richard Herd, I.M.S., Surgeon-General with the Bengal Government, to be C.I.E. Mr. William Fairbank, Mayor of Windsor, 1919–20, Surgeon-in-Ordinary, H.M. Household, Windsor Castle, is promoted to K.C.V.O. In the Order of St. Michael and St. George Dr. Aylmer William May, P.M.O., Northern Rhodesia, is made Companion. In the Order of the British Empire, in addition to the appointments already mentioned, appear the names of Dr. George Adlington Syme, who becomes a K.B.E., in recognition of his services to the State of Victoria; Dr. W. C. Bowling Prendergast, in recognition of his services in combating lead poisoning. Prof. Edward Provan Cathcart, F.R.S., Professor of Chemical Physiology in the Glasgow University; Dr. Andrew Milroy Fleming, Medical Director, Southern Rhodesia; Col. James Crawford Kennedy, R.A.M.C., and Dr. San C. Po, Municipal Commissioner, Bassein, Burma, who become C.B.E.'s; while Dr. Walter Musgrave Eaton, Assistant Medical Director and Medical Superintendent, Ingutsheni Mental Hospital, Bulawayo, Surgeon-Commander Robert William Basil Hall, R.N., Major Frederick Emilius Roberts, R.A.M.C., and Dr. François Auguste Rouget, Medical Superintendent of the Civil Hospital, Mauritius, receive the O.B.E. Dr. Samuel Benjamin Jones, Medical Officer, Anguilla, Leeward Islands, receives the M.B.E. The Kaisar-i-Hind Medal of the First Class for public service in India has been conferred upon Dr. M. R. Ry Pazhamarneri Sundaram Ayyar Chandra Sekhara, Ayyar Avargal, Director of the Tuberculosis Institute and Hospital, Madras, upon Rai Bahadur Upendra Nath Brahmachari, additional physician to the out-patient department of the Medical College Hospital, Bandal, and upon Rai Bahadur Lala Mathra Das, assistant surgeon in the Punjab. We feel constrained to include in our hearty congratulations to these members of the medical profession the name of Mr. T. P. O'Connor, the new Privy Councillor, who, while being the Father of the House of Commons, is also a veteran journalist.

A DIFFICULT DECISION.

THE Law Lords gave their considered judgment last week on the main issue raised in the Court of Appeal on the Russell case. This judgment is set out on p. 1174. There is one comment upon the course and the result of this case which seems not inappropriate here. Medical men are frequently as parties and witnesses made aware of the uncertainty of litigation, and in the latter capacity not seldom have it thrown in their teeth that in respect of some question of scientific expert opinion other witnesses of equal qualification and capacity differ from them. It has from time to time been pointed out in our own columns that it is not for lawyers to blame medical science and its practitioners for this, because they must be aware of a constant and frequent lack of unanimity in the application of legal science by its recognised experts. In the Russell case a particular point of law, vital to both parties, has been decided by an eminent judge, Mr. Justice Hill, in a particular manner. Mr. Justice Hill was upheld in his decision to admit a certain class of evidence by Lord Sterndale, then Master of the Rolls, Lord Justice Warrington, and Lord Justice Scrutton; he has since been further supported by two Lords of Appeal, Lord Sumner and Lord Carson, and none could assert that Lord Sumner is a less learned or a less painstaking lawyer than Lord Birkenhead. Mr. Justice Hill has, however, been over-ruled by Lord Birkenhead, Lord Finlay, and Lord Dunedin, and their decision prevails. When upon a point of law six eminent authorities hold one thing and three others the exact opposite, the views of the three prevailing, so that the six must be treated as having been wrong, it seems fair to argue that divergences of opinion in technical and scientific matters may exist between experts in the science involved, without the holders of divergent views being open to reproach on account of the absence of agreement between them.

RENAL EFFICIENCY IN NORMAL PREGNANCY.

THE question as to how a kidney which shows some slight defect of function will respond to the increased amount of work which accompanies pregnancy is often a very pressing one for the obstetrician. A definite reply must be secured without delay, since clinical or laboratory methods, which involve prolonged investigation, may involve the onset of serious complications before a decision has been arrived at. Dr. G. Barco, assistant in the obstetric clinic at Turin, presided over by Prof. G. Levi, draws attention[1] to the clinical utility of the dilution and concentration test, by which he claims that in the majority of instances, excluding a few doubtful and complicated cases, it is possible to settle the functional inefficiency of the kidney by its incapacity to eliminate water and to estimate the amount of all the waste products and thus establish a kind of balance of the solid material which passes the renal filter. The dilution test brought forward in 1900 by Kowesi and Roth-Schultz consists in the drinking, when the bladder has been emptied, of 1000–1500 c.cm. of water on an empty stomach, and in the estimation during the subsequent four to five hours of the quantity and specific gravity of the urine passed every half hour. Under normal conditions the following characteristics are observed: (*a*) The maximum amount of urine eliminated in half an hour is 500 c.cm. This is of the highest importance, as it is the measure of the maximum velocity of glomerular secretion and by itself alone indicates a good glomerular reaction. (*b*) The elimination of water drunk ends in four hours. (*c*) The quantity of water eliminated through the kidneys in the four hours following its ingestion is never lower than 91 per cent. of the water taken in. (*d*) The specific gravity falls to 1004–1001 in the first two hours pari passu with the marked increase in the urinary amount; after five to six hours it returns to its former figure. (*e*) There is never any increase in body-weight, showing that water is not retained in the organism. Under abnormal conditions it is found that (*a*) the amount of water eliminated every half hour is materially reduced; (*b*) the elimination of water altogether in the four hours after ingestion is decidedly below that taken in, showing that elimination is more or less retarded; (*c*) corresponding with diminished volume there is little decrease in specific gravity. On the basis of these characteristics three types of abnormal behaviour to the test may be distinguished. (1) Retarded type, in which even though all the water introduced is eliminated in four hours, there is delay in the elimination of the greater portion; the initial rapid rise of diuresis is wanting. This condition indicates disturbed renal function. (2) Dangerous type, showing grave functional lesion, in which each portion eliminated is small and equal, even sometimes absent. In the four hours only a few hundred cubic centimetres are eliminated, while the specific gravity is scarcely lowered. (3) Extra renal type, which is met with in cases where, although the renal function is intact, the water tends to pass into the tissues and serous cavities. Although the initial diuresis is rapid and the amount of the first portion eliminated is conspicuous, yet almost all elimination ceases after two hours. But the elimination in four hours is incomplete, because a good deal of water has already penetrated into the tissues and cannot be eliminated by the kidneys. The concentration test is simple. Half an hour after the completion of the dilution test, and again six hours later, a full meal is given without liquid. The urine is collected every two hours, and its specific gravity taken. A healthy kidney under these conditions shows a rapid increase in urinary specific gravity. Should this be small or lowered, renal insufficiency is indicated. By carrying out these two tests in rapid succession it is said to be possible to obtain sufficiently precise information of the total functional renal efficiency. From the diagnosis the next step to prognosis is easy, and it is made possible for the obstetrician to judge how the state of maternity will be supported by the organism. Dr. Larco pleads for a more extended and routine use of these tests. To neglect them would be equivalent to neglecting percussion of the lungs and heart on the ground that the results are capable of varying interpretations and be subjected to influences which may diminish their value. The relative simplicity of the test is certainly a strong reason in favour of its being tried on an extensive scale, and the problem is so grave that trial of such methods is to be strongly advocated.

THOMAS HODGKIN, PATHOLOGIST AND PHILANTHROPIST.

To the current issue of *Guy's Hospital Reports* Sir William Hale-White contributes an informing paper on Thomas Hodgkin, whose name is indissolubly connected with a disease of lymphatic glands. Hodgkin was a notable man in many ways. His father, John Hodgkin (1766–1845), was a grammarian and a tutor to the children of wealthy families. Thomas, born in 1798, was educated at home, becoming fluent in Latin, Greek, French, Italian, and German. He learned his medicine at Guy's Hospital and abroad, graduated M.D. at Edinburgh in 1823, after having, in 1822, attended clinical instruction given by Laënnec at the Necker Hospital, to which circumstance is due the introduction of the stethoscope to Guy's Hospital on his return from Paris. Hodgkin visited Germany and also Rome, where he lodged with a Dr. Viale, who was surgeon to the Inquisition. In 1827 Benjamin Harrison, treasurer of the hospital, determined to make really good the Medical School of Guy's Hospital, now separated from that of St. Thomas. He saw the importance of morbid anatomy and appointed Hodgkin as lecturer, a post which he held until 1837, when the death of Dr. Henry Cholmeley created a vacancy upon the medical staff. For this post Hodgkin and Babbington were candidates and the latter was appointed. Hodgkin then left Guy's Hospital and started in private practice. In 1842 he was appointed lecturer on the theory and practice of medicine to St. Thomas's Hospital School, but his lectures, says Sir William Hale-White, were very diffuse, "and it is difficult to imagine that they fixed the attention of his audience." Besides medicine Hodgkin was always deeply interested in philanthropic works; he was one of the founders of the Aborigines Protection Society, and for many years he used to travel with Sir Moses Montefiore in the East to aid Jews and relieve their miseries. It was on one of these journeys that he contracted dysentery of which he died in 1866 at Jaffa, where his grave is marked by an obelisk of syenitic granite. The work by which Hodgkin is chiefly remembered rests upon a paper read by him in 1832 before the Medical and Chirurgical Society, entitled "On Some Morbid Appearances of the Absorbent Glands and Spleen," which attracted little attention at the time. This is not to be wondered at, for only four of the cases mentioned in the paper were examples of what we now know as Hodgkin's disease, and the writer seems to have laid but little stress upon this case. It was not until Bright, and after him Wilks, in 1856 recognised the importance of Hodgkin's paper that the discovery was properly attributed to him. Wilks, indeed, discovered the disease independently, but directly he found, after reading Bright, that Hodgkin had forestalled him, he hastened to acknowledge his precedence. Among other works of Hodgkin was a volume "Lectures on the Means of Promoting and Preserving Health," delivered at a mechanics' institute about 1830, and setting forth the harm which flows from filth, overcrowding, bad sanitation, horrible houses, drunkenness, bad food, want of vaccination, lack of fresh air, and exercise. Sir William Hale-White has succeeded in making Thomas Hodgkin live again in the minds of the present generation.

OSMICS.[1]

THIS is the second number of a useful little production. The first number of *Osmics*, containing an introduction and 500 bibliographical references, was issued in 1922 and was found useful by many engaged in researches into the difficult subject of olfaction in its many bearings. Between the two issues has appeared the entertaining book by Dr. Dan McKenzie,[2] which has interested many people in what was regarded as an abstruse topic. The issue of a second number of *Osmics* has been prompted by the hope that a further bibliography of the literature on the organs and sense of smell, and on odorous substances, will facilitate and encourage research into the various problems involved. The entries are made without comment of any sort upon the value of particular books or papers, but full references are given, leaving the reader to ascertain whether he has found what he wants. Nothing more has been attempted in the first two issues, but the author suggests that further numbers will appear and possibly summaries of original research into the various aspects of osmics, provided there is an adequate demand for such a "clearing-house." We hope the demand will be obtained, for the value of the publication will be enormously increased by the inclusion of some critical information. Smell has been the least cultivated of the senses, so that there is reason to hope that, if the subject receives something of the attention which has been given to the senses of hearing and sight, the study of odours should reach a higher scientific plane. But one practical point constitutes a difficulty at the beginning. The classification of smells suffers from the absence of the mathematical analysis which can be employed in optics and acoustics. There is consequently no accurate nomenclature of smells, though many attempts have been made to establish some system here comparable to the classification which has been set up in regard to seeing and hearing. Arising out of a report on the treatment of war wounds made by that distinguished veteran, Prof. W. W. Keen, in 1917 at the request of the National Research Council of America, a correspondent in The Lancet pointed out how extremely convenient it would be if it was possible to name the smell of a wound in such a precise way that exactly what was intended could be recognised by investigators at a distance. But the conclusion was arrived at that this would imply the bringing together of smells into a system of scales or octaves which had so far only been attempted with moderate success and in a limited manner, the allusion being to the work of Septimus Piesse in classifying perfumes. Reference is given in *Osmics* to this work, which was published originally some 20 years ago. In it there is set out a series of odours in parallel with the musical scale, the attempt being to show how it should be possible to make a bouquet corresponding to a chord. The gamut of odours thus constructed did suggest a law of octaves according to the investigator's ingenious arrangement, but, as has been pointed out, however, in these columns before, while some persons associate certain colours with smells and others speak of certain musical notes as suggesting corresponding colours, the occurrences are not proved to have any scientific interest.

HOUSING CONDITIONS IN GERMANY.

Prior to the war, housing facilities in Germany were vastly better in the larger towns than in the villages and country generally, especially from a sanitary point of view. Here the rooms of dwellings were small and frequently overcrowded. Nevertheless, on the whole, a quantitative lack of accommodation did not exist, and a qualitative lack only in old-time buildings; any untoward influences were counterbalanced by the presence of open spaces. Since the war, however, owing to the general depression and lack of material building has almost ceased; the housing shortage has been accentuated by the advent of over a million refugees from ceded territories, whilst the birth-rate has, if anything, increased. A comprehensive review of the housing conditions in their relation to social and industrial health has recently been published by Prof. E. Friedberger,[1] director of the Institute of Hygiene at the University of Greifswald. Greifswald is in Pomerania, and the writer considers it a typical example of a small German town. Here the post-war shortage is one of smaller dwellings; only 21·5 per cent. of middle- and lower-class families seeking accommodation were successful in 1920. Students were, and still are to a very great extent, poorly provided for, though a few are given sleeping facilities by well-to-do families. In a large number of labouring-class dwellings and municipal houses chosen at random, it was established that the average room-space was only 7·2 cubic metres (approx. 267 cub. feet) per person, and the window: floor area varied from 1 : 14 to 1 : 69. The rooms were damp, and those used as kitchens were unhygienic and small, serving as bedrooms as well. Ten per cent. had no window at all; in the majority of cases there was no kitchen range. There was one water-tap between five families, representing about 40 persons; bathing facilities were unavailable and sanitary arrangements thoroughly bad. Lighting was provided for by means of petroleum in less than 12 per cent. of cases, in 7 per cent. by calcium carbide, 19 per cent. by tallow candles, 9 per cent. by some oil substitute, in the remainder there was no provision. On an average there were 2·6 persons per bed, for which in 35 per cent. there was no linen. The incidence of disease has decidedly increased, though the relative percentage of tuberculosis is lower than usual, as death occurred rather from enfeeblement due to want of nourishment. Amongst children rickets is but slightly increased, as they are constantly in the sun and fresh air; but their physique is exceedingly poor. The measures adopted by the authorities to combat the housing shortage were planned in 1920, and consisted in building a small number of houses adapted to one and more families. Each dwelling comprises two rooms and a kitchen, which, perhaps not ideal, are at any rate light and dry, and can be heated. Additionally, a small garden is attached, where some live-stock can be kept and a modest amount of vegetables grown. Electric light and water are laid on. The sewage is retained in tanks below the ground, and is used as garden manure. Investigation on the birth-rate showed an average of 6·3 pregnancies per family; 90·5 per cent. of the expectant mothers were unable to avail themselves of the local clinics, owing to their being compelled to work right up to the day of their confinement; 70 per cent. of the total pregnancies ended in live births, the remainder of the infants died shortly before or after delivery; 70·5 per cent. of the infants were nursed by their mothers for varying periods; the same percentage was obliged to be fed at 15 months of age on food partaken of by adults. The hygiene was similarly unsuitable. Such are the conditions under which the present generation in Germany is growing up, and their effects will be only patent in the next few decades.

EPITHELIOMA OF THE TONSIL.

At the last annual meeting of the Medical Society of the State of New York Dr. Leon H. Smith[1] read a paper on epithelioma of the tonsil based on the study of 40 patients who had been treated at the Buffalo State Institute for the Study of Malignant Disease. The cases were divided into the four following groups: (1) cases with the new growth confined to the tonsil and excellent general condition (4 cases); (2) cases with early cervical metastases and good general condition (10 cases); (3) cases with well-marked metastases and poor general condition (14 cases), (4) hopeless cases with advanced toxic cachexia (12 cases). Thirty-six of the patients were males and 4 females. The ages ranged from 28 to 82, the average age being 55. As regards the earlier medical history, only 12 stated that they had had previous attacks of sore-throat or tonsillitis; 75 per cent. admitted excessive indulgence in tobacco, and only three had not used nicotine in any form. Ten had well-marked dental caries, and seven moderate dental caries accompanied by pyorrhœa. In three there were upper and lower plates. In only two patients was the Wassermann reaction positive. The chief complaints were sore-throat and discomfort which were present in at least 50 per cent. A biopsy was performed on each patient, care being taken to remove only a small portion of tissue if dental caries or oral sepsis was present. In the differential diagnosis the following conditions had to be excluded: gummata, tuberculoma, papilloma, sarcoma, and Vincent's angina. The possibility, however, of the coexistence of syphilis or tuberculosis with cancer should not be overlooked. The earlier patients were treated by X rays, but the results in the vast majority were unsatisfactory, retrogression of the neoplasm and improvement of the general condition being only temporary. During the last three years a combined method of treatment has been adopted. Radium emanations in glass beads are inserted into the growth where they are allowed to slough out or remain encysted, and deep X rays or the new radium pack are applied to the cervical regions. Apart from cases of a fulminating type, patients in whom the symptoms had lasted one to three months only were favourable subjects for treatment. After the lapse of three months the cases became more refractory to treatment and after six months altogether inoperable. Seventeen patients in the present series died from hæmorrhage, two from general sepsis, four from suffocation due to œdema of the glottis, and three from profound toxæmia. In conclusion, Dr. Smith emphasises the importance of early diagnosis and the prompt institution of radiation therapy.

DOMINIONS MEDICAL HOSPITALITY.

THE Dominions Hospitality Committee, Sir William Hale-White, President, has arranged its programme for the entertainment of overseas visitors. The appended list has been circulated to all visitors who have registered their names, and these are requested to reply as soon as possible, indicating the functions which they would like to attend.

Programme.

June 13th: Address by Sir Almroth Wright and visit to his laboratories at St. Mary's Hospital, Paddington, at about 4 P.M.

June 20th: 8.15 P.M., Kensington Town Hall, Cavendish Lecture by Sir Robert Jones, followed by conversazione by the West London Medico-Chirurgical Society.

June 23rd: 2.15 P.M., visit to Greenford (Messrs. Lyons and Co., Ltd., works). Charabancs to leave 1, Wimpole-street, 2.15 P.M. Tea provided.

June 26th: Visit to the laboratories of Messrs. Parke Davis, at Hounslow. Luncheon and tea at Hounslow. Dr. J. Stanley White will give a demonstration of matters of pharmacological interest. Charabancs will leave 1, Wimpole-street about 12 noon. Return via Windsor.

June 30th: Reception and ball in the Guildhall by the Corporation of London.

July 8th: Dinner at the Apothecaries' Hall, by the Society of Apothecaries.

July 9th: Luncheon at the Town Hall, Portsmouth, by invitation of the mayor, followed by a tour arranged by the naval authorities (leaving London in the morning, and returning in the evening).

July 17th: Luncheon by THE LANCET.

Visit to Lord Mayor Treloar Cripples' Home, Alton. (*Date to be arranged.*)

Visitors who have not received the above notice should inform the Hon. Secretaries, Mr. A. E. Mortimer Woolf, 94, Harley-street, W. 1, or Mr. E. T. C. Milligan, 86, Harley-street, W. 1, as soon as possible.

FLUELESS GAS STOVES.

THE report of the joint committee, formed by the Society of Medical Officers of Health and the Royal Sanitary Institute to consider the use of gas stoves for domestic and workshop heating where no provision is made for the escape of flue gases to the outer air, has now been issued. The Society of Medical Officers of Health was represented by Prof. H. R. Kenwood, Dr. D. C. Kirkhope, Dr. F. N. Kay Menzies, and Dr. E. H. Snell, and the Royal Sanitary Institute by Prof. A. Bostock Hill, Dr. J. S. Owens, Dr. L. C. Parkes (chairman), Mr. J. Osborne Smith, and Mr. H. D. Searles Wood. Much valuable information on the use of flueless gas stoves was received from medical officers of health of large cities, including the cities of London, Glasgow, Liverpool, Nottingham, Leeds, and from the metropolitan borough of Stepney. Dr. J. S. Owens submitted for the consideration of the committee a report on flueless gas fires from a hygienic aspect, to which special attention is drawn. He discusses the products of combustion and the questions of humidity, ventilation, and losses in flue, and comes to the following conclusions as to the use of flueless fires: (*a*) There is a problematical saving of up to 30 per cent. in heating efficiency by abolishing the flue; (*b*) the quantity of CO_2 and water in the air of a room are greatly increased; (*c*) sulphur in the gas contaminates the air in the form of SO_2 or SO_3; (*d*) the ventilating effect is practically nil; (*e*) if there is a leakage or the gas tap is not fully closed, the gas escapes into the room; (*f*) if combustion is imperfect owing to wrong design, the stove going out of order, or being incorrectly used, poisonous products—such as CO—escape into the room; (*g*) there is a great temptation for users to restrict ventilation purposely so as to economise heat. From the evidence submitted to them the committee are of opinion that whilst there is little or no evidence of any injurious effects upon health by the use of these flueless gas stoves under ordinary conditions—i.e., where the rooms are of fair size, sufficiently ventilated, and not overcrowded—there is always an element of risk of the escape of CO gas into the room, as pointed out in (*e*) and (*f*) of Dr. Owens's summary. So convinced are the committee of the necessity of a very free ventilation existing where flueless gas stoves are in use that—bearing in mind the usual absence of this free and effective ventilation in living rooms, bedrooms, workrooms, &c.—they think it desirable to discourage the introduction of these stoves and to express the opinion that their use can only be justified in such places as entrance halls, passages, and landings, where ventilation is free and where occupants do not remain for any considerable length of time.

INDUSTRIAL FATIGUE RESEARCH.

EACH succeeding annual report, and this is the fourth, of the Industrial Fatigue Research Board tells of progressive advance in the organisation and methods employed in this difficult field of research. New facts brought to light continue to support those obtained by earlier work, so that gradually the principles underlying human activity are being ascertained. Industrial depression during the past two years has militated against the gathering of much useful information under normal conditions; but the opportunity has been seized upon for following up problems by intensive laboratory research. An instance is the value of interpolating short rest pauses during long spells of work, already studied on light repetitive work; here laboratory and industrial observations confirm one another and indicate a beneficial effect upon output from rest pauses scientifically used. Investigations are in progress into such general subjects as accident causation, the design of machinery, the physiology of ventilation, sickness, and mortality, while research has been conducted into the principles governing muscular action, weight carrying, and tests for physical efficiency, and is being pursued into vocational selection, the legibility of type, and other matters. Clearly the scope of the work is wide, and the need for it great. In addition to a general review, the report contains contributions from individual investigators; the first of these, by Miss M. Smith, is a clever survey of psychological problems confronting an investigator in industry; we seem to know the explosive manager whose inflated egotism is easily wounded, the over-anxious man with much irritability and little self-reliance, and that other one whose obsession is tidiness; and, on the other side, the truculent worker resentful of criticism, the ultra-weak worker with lost individuality, and the one who welcomes monotony as providing free scope for mental fancies. Each and all these personalities react differently and interfere with the validity of data collected for measuring output. Mr. E. Farmer, in a discussion of the method of grouping by differential tests, presents a disquisition on logic in which the principles associated with the name of Jevons are displayed under a new nomenclature in an industrial environment; nevertheless, the presentation of the subject is good and useful. An excellent case is made out by Mr. S. Wyatt for establishing schools of training for industrial operatives, particularly for cotton-weavers; he shows that existing methods of training are haphazard, inefficient, and uneconomical, and rightly points out that everyone "possesses abilities which are more suitable for one industrial process than another, and it becomes necessary to consider the possibilities of finding for each individual the industrial task most suited to his requirements." The last contribution is by Dr. H. M. Vernon, and deals with the use and significance of the kata-thermometer; although it is rather technical in places, it is a clear and readable exposition of the subject.

Dr. John Parkinson will give the address in medicine before the Canadian Medical Association at their fifty-fifth annual meeting to be held at Ottawa from June 17th to 20th. The subject of his address will be the Diagnosis of a Healthy Heart.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LXXIV.—TREATMENT OF GLAUCOMA.

THE most useful classification of glaucoma from a practical point of view is (1) secondary glaucoma, (2) primary chronic glaucoma, (3) primary acute glaucoma.

By secondary glaucoma is meant glaucoma which occurs as a complication or as a result of some other disease of the eye; thus an intra-ocular neoplasm, repeated attacks of iritis or cyclitis, or thrombosis of the central retinal vein may be the responsible cause. The subjects of such conditions will mostly have been under special care for the primary disease and the possibility of the complication will have been anticipated; I do not, therefore, propose to deal with this group.

Primary glaucoma is more common in females and is of unusual occurrence before middle age; myopes are in large measure immune from it and hypermetropes are predisposed to it. The essential feature of the disease is an increase of the intra-ocular tension, even though in chronic cases the increase may be present for short periods only during the day, and thus easily overlooked. If we consider the course of the aqueous flow within the eye, we see that it is secreted into the posterior chamber of the eye by the columnar cells which clothe the ciliary processes; some of it infiltrates the vitreous body, but the greater part passes forward over the front of the lens, through the pupillary aperture into the anterior chamber, and leaves the globe by filtering into the crypts of the iris, and by gaining access to the canal of Schlemm and the spaces of Fontana through the angle of the anterior chamber.

There are three chief points at which this circulation may be obstructed: (*a*) The ciliary processes may become so swollen that they come into contact all round with the margin of the lens, the vitreous chamber being completely shut off from the aqueous chambers; the vitreous will swell, the lens, and with it the iris, will be pushed forward, making the anterior chamber more shallow, tending thereby to close the angle of the chamber and so to obstruct the exit of the aqueous from the eye; this is believed to be the course of events which leads up to the occurrence of an attack of acute glaucoma. (*b*) The second point of possible obstruction is at the pupillary aperture. After repeated attacks of iritis the iris may become so completely stuck to the lens upon which it rests that the flow of aqueous through the pupil is prevented; in this case the posterior chamber becomes distended, the iris becomes bulged forwards (iris bombé), and so the angle of the anterior chamber becomes occluded; this would be an example of secondary glaucoma. (*c*) A third point, the angle of the anterior chamber, is the site of obstruction in primary chronic glaucoma; the anatomical configuration of a small hypermetropic eye, with a relatively large lens and a shallow anterior chamber, and the increased size of the lens as age proceeds, are predisposing causes, factors causing an anterior chamber, which from the first was shallow, to become still more shallow.

Primary Chronic Glaucoma.

The reduction in depth of the anterior chamber which results from the growth of the lens is an exceedingly gradual process, and the period of transition between the point at which the exit of the aqueous is efficient and the point at which it becomes no longer quite adequate is thus a very gradual transformation; the onset of the disease is correspondingly insidious, and symptoms in the early stages are fleeting and unobtrusive.

Diagnosis.—In a number of cases the cornea is obviously so small and the anterior chamber so shallow that it is clearly necessary to exclude glaucoma, even though no symptoms may be present. There may be a history of attacks during which objects are seen as through a mist, or as if the room was filled with smoke, or, owing to corneal œdema, lights may appear to be surrounded by wide rainbow-coloured haloes; such symptoms as these are very suspicious. There may be complaint of rapidly increasing difficulty with reading. The optic disc, being a weak part of the tunics of the globe from its being perforated by the bundles of the optic nerve fibres, becomes herniated backwards, producing the so-called glaucomatous cupping, and there is developed a constriction of the visual fields which is most marked at the upper nasal side.

Treatment.—It is sometimes assumed that a high general systolic blood pressure is likely to cause a heightened intra-ocular tension, and that therefore reduction of the blood pressure should have a part in the treatment of such cases. In this connexion I have shown that there is good reason for believing that a pressure in the brachial artery of, say, 220 mm. does not imply that the pressure in vessels of the size of those within the eye is at all raised; secondly, I have shown that taking primary glaucoma patients as a class, they do not have blood pressures above the normal for individuals of their age, and on the other hand, that as a class, patients with very high blood pressures show no increase of intra-ocular tension; and thirdly, a view which has many adherents is that in a majority of individuals it is not possible greatly to lower the systolic blood pressure except by methods which are so drastic as to disturb very seriously the general constitutional well-being. In spite of what has been said above, I need hardly insist that anything which advances the bodily or mental welfare of the patient is greatly to be advocated in the treatment of the disease we are considering.

Local Treatment.—All local treatment is directed against the intra-ocular tension. There will always be a certain number of cases where operative treatment for various reasons is not available, as, for example, ill-health or infirmity, unwillingness on the part of the patient to submit to operation, and so non-operative treatment has to be resorted to. In non-operative treatment the one drug that is of value is eserine; by causing contraction of the pupil it drags the iris away from the angle of the anterior chamber, and so does what is possible to relieve this channel of exit of any obstruction which a dilated pupil, with its accompanying thickened iris, might produce. The drug is usually used in the form of ¼ per cent. solution of the sulphate to be dropped into the eye night and morning, or, if attacks of mistiness occur at regular times of the day, it is well to anticipate such attacks by using the drops a little beforehand. Excessive reading should be avoided, and a protection against bright light by means of tinted glasses is advisable. The best prospect of arresting the disease is by means of operation. All modern operations have for their object the relief and prevention of the high intra-ocular tension, and to this end the formation of a permanent fistulous communication between the anterior chamber and the subconjunctival space is aimed at so that the aqueous filters slowly away amongst the subconjunctival tissues in addition to its normal route of exit. The operation most in vogue is that of sclero-corneal trephining. I have recently introduced a small modification which gives improved results—namely, the careful sewing up of the conjunctival incision with a fine and accurately applied continuous silk stitch, so as to make the incision watertight from the first.

Acute Glaucoma.
